treated group that has the same survival as an age-adjusted peer population,” he estimated that over 80% of women with tumors less than 1 cm in size were curable and that this was manifest at 10 years of follow-up. In summary, he once again stressed the importance of local control for small tumors, while emphasizing the importance of systemic control in breast cancer.

CLINICAL PRESENTATION OF BREAST CANCER

Today the most common presentation is with an abnormal mammogram, although patients continue to present with a painless or slightly tender breast mass. In younger women, a delay in diagnosis may be attributed to benign causes, such as recent trauma or changes with pregnancy, or due to breast-feeding. For those women presenting with a mass, the patient may ultimately present with breast tenderness, skin changes, bloody nipple discharge, or changes in the shape and size of the breast, with or without axillary adenopathy. Rarely will women present with axillary nodal disease but no evidence of a breast primary, otherwise known as occult breast carcinoma. Lastly, inflammatory breast cancer (IBC) presents as a tender, red, and swollen breast, often mistaken for mastitis. A crusting rash emanating from the nipple is *sine qua non* for Paget's disease of the breast, which is almost uniformly associated with an underlying malignancy. Fortunately, with the increase in screening following publication of the NIH Consensus Statement in 1978, patients rarely present with metastatic disease (24).

IMAGING STUDIES OF THE BREAST

Introduction

Breast imaging can be performed as a screening tool in asymptomatic women to detect early cancer, in high-risk women, or as a diagnostic examination in women suspected of having breast cancer or previously treated for breast cancer. Mammography, an X-ray examination of the breast obtained either by conventional film or by digital technique, remains the most widely used technique for screening and is the only modality proven to decrease mortality. The benefits of screening mammography and the differences between film and digital technique will be discussed. The reported benefits of digital mammography in selected groups of women will be presented. Computer-aided detection (CAD), a tool designed to help the radiologist improve the detection of breast cancer, is frequently used by interpreting radiologists; the benefits and consequences will be reviewed.

Modalities such as ultrasound (US) and magnetic resonance imaging (MRI) serve as adjunct tools in the diagnostic setting or high-risk screening. An emerging technology, breast tomosynthesis, has recently been approved by the United States Food and Drug Administration (FDA) for clinical use in patients. A review of this potentially revolutionary tool will be presented.

Mammography

The purpose of screening mammography is earlier detection of clinically unsuspected breast cancer in asymptomatic women. The efficacy has been widely established by multiple randomized controlled trials demonstrating absolute mortality reduction, achieved by mammography's ability to detect both ductal carcinoma *in situ* (DCIS) and invasive breast cancer at a smaller size and earlier stage than in unscreened groups of women. Screening mammography is associated with an 18% to 45% reduction in breast cancer mortality compared with unscreened

groups (1–3). Many of the trials were performed in Swedish populations, one study including analysis of 2,044 breast cancer deaths from 14,092 incident tumors, spanning over 7.5 million person-years (1). These studies have analyzed large-scale populations with and without screening over long time intervals.

For the past decade, based on these trials annual screening mammography in women beginning at 40 years of age has been recommended by the American Cancer Society (ACS), American College of Radiology (ACR), and most national medical societies (4). In November 2009, the United States Preventive Services Task Force (USPSTF) published a highly controversial statement with new recommendations for screening for breast cancer (5). Their new recommendations are:

Biennial screening mammography for ages 50 to 74, against routine screening mammography in women aged 40 to 49, with decision to start before age 50, based on individual risk factors, and to involve a discussion with a health care provider, against breast self-examination.

The new guidelines caused an upheaval in the medical community, with primary-care physicians unclear as how to guide their patients, and patients unsure of whether they should be screened at ages 40 to 49. The task force recommendations against routine screening at ages 40 to 49 are cited on the “harms” outweighing the benefits in this age group. Since there are fewer cancers in this age group, there are fewer lives saved with screening, with the “harms” of anxiety and distress over false-positive results, additional imaging studies, and biopsies said to be too significant to recommend routine screening. The USPSTF estimates the “number needed to invite for screening to extend one woman’s life” as 1904 for women aged 40 to 49, and 1,339 for women aged 50 to 59. The radiology community strongly disagrees with the USPSTF conclusion that there is not enough benefit in screening women in their 40s to warrant the “undue stress.”

Rebuttals by the radiology community, including the ACR and Society of Breast Imaging (SBI) as well as the American Congress of Obstetricians and Gynecologists (ACOG) and the National Cancer Institute (NCI) called the new recommendations “a step backward,” representing significant harm to women’s health, and raised concern that if adopted by the American public, they would result in needless deaths (6–8). Although the number needed to screen is higher in women in their 40s (1,904) than in their 50s (1,339), there is still sufficient benefit to those in their 40s to offer annual screening. At this time, screening based on risk is unfounded, since 75% of women diagnosed with breast cancer have no identifiable risk factors; screening only those with known risk factors will miss most of the women who will develop breast cancer (9).

Prior to 1997, controversy existed regarding screening mammography in women 40 to 49 years of age. This was largely due to most of the earlier trials not including enough women in this age group to demonstrate a statistically significant reduction in breast cancer mortality from screening. Subsequent studies (1,10) included a large enough population to demonstrate the benefit of screening this age group. The cost-effectiveness of age-related screening mammography has been assessed using the Markov model. The marginal cost per year-life saved (MCYLS) varies from \$18,800 to \$16,100 for age groups including women ages 40 to 79, within the range of other generally acceptable diagnostic and therapeutic medical procedures (10).

Therefore, current recommendations for screening remain unchanged: annual screening mammography for women beginning at age 40.

It is important to recognize that not all cancers will be found by mammography, the sensitivity being approximately 80% to 90%. Therefore, up to 10% to 20% of cancers will not be visible mammographically (11–13), largely because of insufficient contrast between normal and abnormal breast tissue. In a screening population, up to 10% of patients will be “recalled”

for additional imaging—either additional mammographic views, spot compression views to determine if the area represents superimposed tissue versus a true mass or magnification views to better characterize calcifications, or US evaluation to determine the solid or cystic nature of a mass. Of all positive screening examinations, approximately 5% to 10% will have a diagnosis of cancer. Of all recommended biopsies, 25% to 40% will be positive for cancer. It is anticipated that the addition of tomosynthesis to two-dimensional conventional mammography will effectively decrease the “recall” rate and positive screening rate, and decrease the anxiety caused to patients. It is also expected to increase the sensitivity of mammography.

Mammography Regulations and Reporting

Mammography practice in the United States is rigidly regulated by the FDA under the Mammography Quality Standards Act (MQSA) of 1992 (14). The MQSA tightly regulates mammography, requiring extensive follow-up and outcome monitoring of all facilities and interpreting radiologists. Recall rates, biopsy recommendations and results, and cancer detection rates must be analyzed for each interpreting radiologist. Cancer staging must be recorded to include histologic type, size, nodal status and grade. MQSA requires analysis of any known false-negative mammograms. Requirements include that the facility must send a letter to each patient informing her of the results of her mammogram, in addition to a formal report to the referring physician. It is federally mandated that the report include a final assessment category providing guidance and management recommendations.

The Breast Imaging Reporting and Data System (BIRADS), first published in 1993, is a lexicon developed by the ACR to standardize terminology used in reporting findings on mammograms (15). It includes terms for describing features of masses (shapes and margins) and calcifications (morphology and distribution). It defines final assessment categories to describe the radiologist’s level of suspicion about a mammographic abnormality, to comply with the federally mandated MQSA regulations (15). All mammograms must be assessed with a final BIRADS category of 0 to 6 (Table 28.2).

The report must include the date of comparison films, the indication for the examination (screening, recall, clinical finding, or follow-up), an assessment of overall breast composition to indicate the relative possibility that a lesion may be hidden by normal tissue limiting the sensitivity of the examination (Table 28.3), a description of any significant findings, and an overall summary impression.

Mammographic Technique and Findings

The screening mammogram is an X-ray of the breast, with two views of each breast obtained: a top-to-bottom, or cranio-caudad (CC) view, and an angled side-to-side, or mediolateral oblique (MLO), view. The breast is pulled away from the body, compressed, and held between two plates while the image is obtained. The images can be recorded on film or stored digitally on a computer. Two views of each breast are needed to optimize the amount of breast tissue included on each mammogram, to minimize overcalling disease because of superimposed tissue on a single view, and to decrease the likelihood of obscuring a cancer by overlapping tissue on a single view. In some patients, particularly those with larger breasts, more than 4 views are obtained by the technologist to ensure that all the breast tissue is included on the images.

A mammographic mass is defined as a space-occupying lesion seen in two projections, whereas an “asymmetry” is a potential mass seen only in a single projection. For masses, the shape, margins, and density may be described. Masses which are irregular in shape, with indistinct or spiculated margins, and

Table 28.2 BIRADS (Breast Imaging and Reporting Data System) Assessment Categories

Category	Interpretation
0	Mammographic assessment is incomplete Needs additional imaging evaluation and/or prior mammograms for comparison Used in screening situations
1	Negative No mammographic evidence of malignancy
2	Benign finding(s) “Normal” assessment, but describes a benign finding No mammographic evidence of malignancy
3	Probably benign finding—initial short interval follow-up suggested Finding with <2% risk of malignancy, not expected to change over interval
4	Suspicious abnormality—biopsy should be considered Findings do not have classic appearance of malignancy, but greater probability than Category 3
4A	Finding needs intervention but with low suspicion for malignancy
4B	Findings with intermediate suspicion for malignancy
4C	Findings with moderate suspicion for malignancy, but not classic
5	Highly suggestive of malignancy—appropriate action should be taken Finding had greater than 95% probability of being malignant
6	Known biopsy-proven malignancy—appropriate action should be taken Used for lesions identified on imaging studies with biopsy proof of malignancy prior to definitive therapy

Note: It is federally mandated that all mammography reports give a final assessment category.

of high density are the most worrisome for malignancy, whereas round or oval masses with circumscribed (well-defined) margins are more likely benign. Calcifications can be described by type and distribution. Those that are larger, coarser, smoothly marginated, and more easily seen are likely benign, as opposed to those that are very fine, pleomorphic (varying in size and shape), or linear, which are more likely to be malignant. The distribution may be telling, as the diffuse and scattered calcifications are more likely innocent, and those grouped or clustered, arranged in a line (linear), or segmental fashion are more worrisome. The size of any abnormality, location by quadrant or clock-face, and depth should be included in the description. Associated findings suggestive of malignancy, or secondary signs of malignancy, are skin retraction, nipple retraction, skin thickening, trabecular thickening, axillary lymphadenopathy, and architectural distortion.

Table 28.3 Mammographic Assessment of Overall Breast Composition. The Overall Assessment of Volume of Attenuating Tissues in Breast, which Indicates the Relative Possibility that a Lesion is Hidden by Normal Tissue and Indicates the Sensitivity of the Examination

Mammographic Description	Glandular Proportion of Total Breast Tissue
The breast is almost entirely fat	<25%
Scattered fibroglandular densities present	25%–50%
The breast tissue is heterogeneously dense; this may obscure detection of small masses	51%–75%
The breast tissue is extremely dense; this may lower the sensitivity of mammography	>75%

Diagnostic Mammography

Diagnostic mammography is reserved for women with clinical signs or symptoms that suggest breast cancer (palpable mass, skin thickening, nipple retraction, or nipple discharge). Recalls occur when patients are recalled for further mammographic evaluation because of an abnormal screening examination or personal history of breast cancer. Patients with breast augmentation may be considered diagnostic because of more effort and time involved with obtaining necessary views, but should be audited in the screening group.

Film versus Digital Mammography

Film mammography is extremely effective and has been widely accepted as a screening modality for the past 20 to 30 years. With this technique, the mammography images are recorded as hard copy on film and developed by the technologist, then presented to the radiologist for review. Digital mammography uses a digital detector to replace the screen-film of conventional mammography. Radiation transmitted through the breast is absorbed by an electronic detector, with a response faithful over a wide range of intensities. The recorded information can be displayed using computer image-processing techniques to allow arbitrary settings of image brightness and contrast without need for further exposure to patients. The lower system noise would be expected to enhance the visibility of subtle contrast differences between tumors and normal background tissue. The processes of image acquisition, storage, and display are separated, allowing optimization of each (16,17). The average patient dose of radiation is slightly lower than that of film mammography. Examination time for each patient is shorter, permitting increased patient throughput. Images are more easily archived and accessed in picture archiving and communication systems (PACS). The disadvantages of digital mammography are cost of equipment. The cost of a digital system is 1.5 to 4 times as much as a film system (18).

Early clinical trials showed only equivalent diagnostic accuracy between digital and screen-film mammography (19–24). The Senographe 2000D screening trial demonstrated a significantly significant decrease in recall rate for digital (11.8%) versus screen-film (14.9%), as well as a decrease in biopsy rate (19).

However, more recently, the results of the Digital Mammographic Imaging Screening Trial (DMIST) have been published in the *New England Journal of Medicine* demonstrating a benefit of digital over screen-film mammography in certain groups of women (18). In this study, 49,528 asymptomatic women presenting for screening mammography at 33 sites in the United States and Canada underwent both digital and film mammography, with the examinations interpreted independently by two radiologists. While in the entire population, the diagnostic accuracy of digital and film mammography was similar, the accuracy of digital mammography was significantly higher than that of film mammography in the following groups: women under the age of 50 years; women with heterogeneously dense or extremely dense breasts on mammography; and premenopausal or perimenopausal women. This is felt to be a significant study in the radiology community because the increased density seen on mammography is known to decrease the sensitivity of the technique in these patients (25,27), who have also been shown to have an increased risk of breast cancer because of their breast density (26–29). The results are understandable because the technical advantages of digital mammography permit X-ray transmission manipulation to enhance visualization of subtle changes in tissue over the entire breast. It is known that the major limitation of mammography is that cancer can be hidden by adjacent breast tissue; with digital mammography, the visibility of a mass or cancer present in an image can be increased if contrast is adjusted.

The effect of transition to digital mammography from film screen has been more recently studied (30). An audit of the practices data from baseline year of film screen, year 1 digital, year 2 digital, and year 3 digital was examined. In this practice, there was an increase in the recall rate with digital mammography (6.05 recall rate with film screen, to 7.1% to 8.5% with digital technique), which persisted as a higher rate even at year 3. However, the cancer detection rate also increased for at least 2 years after the transition to digital, suggesting that cancers were more often obscured with film screen mammography than were visible by digital technique. Overall, calcifications were significantly better seen by digital technique, an important point because calcifications often mark earlier, more treatable disease.

Computer-Aided Detection

CAD, approved by the FDA in 1998, identifies suspicious findings on mammograms to assist the radiologist's interpretation. Initial studies demonstrated increased sensitivity of cancer detection when CAD was added to screening programs, at a cost of increased recalls and increased rate of biopsy (31–33). Increased rates of cancer detection were reported at between 7.62% and 19.5% (34–37). Cupples et al. showed a particular improvement of small cancer detection by CAD, with a 164% increased cancer detection rate of invasive cancers less than 1 cm (37). Because of the reported improvement of breast cancer detection, Medicare and many insurers reimburse for use of CAD.

A larger-scale study conducted by Fenton et al. determined the association between use of CAD at mammographic facilities and performance of screening mammography during 1998 to 2002 (38,223,135); women were screened at 43 facilities in 3 states, with and without the assistance of CAD. The specificity of screening decreased from 90.2% without CAD to 87.2% with CAD, while the biopsy rate increased by 19.7% with CAD. There was no statistically significant change in sensitivity with or without CAD, although there was a trend towards an increase in sensitivity. Overall, the increased rate of biopsy resulting from use of CAD was not clearly associated with improved detection of invasive cancer. However, it should be noted that CAD was used more by community radiologists than academic radiologists in this study, which may account for some of the differences reported by others. Of the cancer detected by CAD, there was a trend towards more DCIS detection than invasive cancer,

which may be more clinically important as early detection may decrease mortality. Although there were a large number of women included in the study, the number of cancers was still relatively small, making it more difficult to judge whether the benefits of routine use of CAD outweigh its harms.

Ellis et al. (39) compared detection of small (less than 16 mm) invasive cancer by two different, FDA-approved CAD systems commercially available and demonstrated a statistically significant higher sensitivity for R2 than for iCAD Second Look.

Results from the Computer Aided Detection Evaluation Trial II (CADET II) study (40) demonstrate that double reading versus single reading plus CAD of mammographic exams are equivalent. This randomized, multicenter prospective study analyzed 227 cancers detected in 28,204 women by lesion type. Overall, there was no significant difference in the double reading regimen versus the single reading with CAD regimen for identification of masses or microcalcifications. However, more parenchymal deformities were detected in the double reading regimen, while more asymmetric densities were found by single reading plus CAD. In addition, there was a significant trend for improved cancer detection in women with dense breasts with double reading.

An analysis of prospectively overlooked CAD marks on prior screening mammograms in women subsequently diagnosed with breast cancer consisted of 50,100 screening mammograms over a 3-year time interval (41). A total of 75 mammograms of women subsequently diagnosed with breast cancer were analyzed by 3 radiologists. These mammograms were initially interpreted using CAD as negative. In 61%, the mammograms had visible findings in retrospect, with 46% determined actionable and 54% under-threshold; CAD correctly depicted 64% of these visible findings and also demonstrated a higher sensitivity for actionable findings (90%) than under-threshold (60%). CAD more often marked the actionable findings on both views (58%) versus under-threshold (27%). This suggests that when a finding on a screening mammogram shows a CAD mark on both the cranioaudad and MLO views, more attention should be paid.

The use of CAD has increased across the country by radiologists. An examination of the database of the nationwide Medicare Part B fee for service from 2004 to 2008 (42) found that by 2008, CAD was used in three-fourths of all screening and half of all diagnostic mammography examinations in the United States. CAD was used more often in the private office setting than in the hospital setting. "Double reading," demonstrated to increase cancer detection, is costly and time consuming; CAD may be a reasonable alternative. CAD is likely to continue to be used and may replace "double reading" currently in practice at some institutions.

Ultrasound

Ultrasonography is a valuable adjunct to mammography, largely due to being widely available and relatively inexpensive. It is usually used clinically as a targeted examination, most often to determine the cystic versus solid nature of a mass. It has been shown to be effective in determining features of masses to determine likelihood of benign versus malignant (43). Prevalence screening studies in women with radiographically dense breasts have shown that 3 to 4 cancers/1,000 women are detected by US only (43–48). However, the limitations of breast US as a screening tool are well known, as it requires a skilled operator, is labor intensive, and lacks standardized examination technique and interpretation criteria. Moreover, it does not detect microcalcifications, which can signal the earliest forms of cancer, the *in situ* disease. It has a high false-positive rate (44–47) and is less sensitive than breast MRI. Given these factors, it is unlikely that screening breast US will become widely used in the United States, particularly with the more sensitive breast MRI availability and recent FDA approval of tomosynthesis.

Tomosynthesis

Tomosynthesis is a 3-dimensional mammographic technique allowing better visualization of breast lesions by minimizing effects of overlapping tissue. The acquisition of images mimics conventional mammography with breast positioning and compression. Multiple low-dose images are obtained at different angles during a sweep of the X-ray tube, resulting in a digital data set which can be reconstructed into tomographic sections through the breast. Digital breast tomosynthesis (DBT) was approved for clinical use in February 2011.

A single vendor, Hologic, received FDA approval for Combo mode, requiring both conventional two-dimensional digital mammography in 2 projections (craniocaudal and MLO) to be obtained in the same compression with 3-dimensional tomosynthesis images. There is no additional positioning involved for the patient.

The limitations of conventional mammography are low-positive predictive value and low sensitivity, primarily because normal breast tissue elements outside of the plane of interest can obscure an abnormality, or superimposed tissue elements may give the appearance of an abnormality. It is expected that tomosynthesis will reduce false-positive mammograms, and thus decrease the recall rate, because it would minimize the effects of overlapping tissue.

Poplack et al. (49) compared the image quality of tomosynthesis with conventional mammography and estimated the recall rate of screening when tomosynthesis is used in addition to mammography. Ninety-eight women with 99 screening recalls were evaluated with tomosynthesis of the affected breast. The image quality of tomosynthesis was found to be equivalent in 52% and superior in 37% of patients. Also, many findings would not be recalled with tomosynthesis, allowing a reduction in recall of 40%. Masses were better seen on tomosynthesis because of recognition of tissue overlap. Calcifications were better seen on diagnostic mammography, accounting for most of the cases in which tomosynthesis was of inferior quality. This may be due to motion related blur due to the somewhat long (19 seconds) exposure time of the tomosynthesis, and also because in this study, the images were reconstructed at 1 mm slice thickness, which may be too thin to show the clustered distribution of calcifications. It will likely be needed to include a thicker reconstruction in the data set to permit better visualization of calcifications. It is believed that tomosynthesis will have more impact in women with dense breast tissue.

As currently approved for clinical use, tomosynthesis is performed in two projections. Rafferty (50) presented data on 34 patients scheduled for biopsy by performing tomosynthesis in both the CC and MLO projections, finding that most lesions (65%) were equally visible on both, but 9% were only seen on the CC view and would have been missed by the MLO view alone; all of these potentially missed lesions were malignant. The available data suggest tomosynthesis will require imaging in both projection for optimal lesion visualization.

Preliminary data suggest that tomosynthesis will improve screening mammography, and that it may also be an important diagnostic tool. In a subjective side-by-side review of 25 cases by 4 interpreting radiologists, Hakim et al. (51) compared the use of two-dimensional digital mammography with either tomosynthesis or additional spot compression views in the diagnostic setting. The combination of two-dimensional mammography with tomosynthesis was rated better or equivalent to conventional diagnostic workup in 81% of lesions observed. In 12% of cases, the use of tomosynthesis would eliminate the need for US. Noroozian et al. (52) evaluated the use of tomosynthesis in the diagnostic workup in 67 masses, comparing tomosynthesis to conventional spot compression views. Their preliminary findings suggest the additional mammographic views may not be necessary to characterize masses when tomosynthesis becomes

clinically integrated. The utility of additional mammographic views (recalls) was well established in the late 1980s and has been the mainstay of diagnostic breast imaging for mass characterization. These spot compression views reduce the superimposition of overlapping tissue, enhancing margin visibility and image detail. However, the recall examination induces much anxiety in many patients, causing criticism of traditional mammography over the years. The addition of tomosynthesis in the screening setting is expected to notably decrease the call-back rate.

Tomosynthesis is currently being implemented in larger imaging centers across the United States. It is expected that within a few years there will be more data available to better determine the utility of tomosynthesis. It is unknown whether there will be additional cost or reimbursement for the procedure. The technique as of now is being reimbursed as for two-dimensional digital mammography. However, the equipment is expensive and the reading time for the radiologist is increased, with additional images to be interpreted. As more breast imagers become adept at the technology, a clearer sense of the increased reading time will be available.

Given its ability to minimize the effects of overlapping tissue, tomosynthesis is expected to be more beneficial in women with dense breasts, and may not yield more information in women with fatty breast tissue, where lesions are less likely to be obscured by overlapping tissue. However, more large-scale trials will need to be performed to evaluate who will best benefit from the examination.

Breast MRI

MRI of the breast has evolved over the past 2 decades, from a research tool to the most sensitive imaging modality in the detection of breast cancer. Contrast-enhanced breast MRI is the most accurate modality in the clinical evaluation and staging of breast cancer (1). For breast lesion detection, intravenous injection of Gadolinium-based contrast enhancement allows visualization of breast cancer against the background of glandular tissue. This distinction relies on the determination that tumor angiogenesis and surrounding tissue permeability allow contrast uptake within cancer (2). That is, a significant number of invasive tumors demonstrate rapid wash-in of contrast by 2 minutes and wash-out with time (3). Significant overlap between the enhancement pattern of benign and malignant processes exists, which must be recognized, and which lowers the specificity of breast MRI. In addition, background enhancement works against lesion detection by obscuring abnormal areas of enhancement, particularly in premenopausal women, due to the hormonal effect on the glandular tissue. Therefore, to minimize this effect, it is recommended to image premenopausal women during days 7 to 14 of the menstrual cycle for routine breast MRI exams.

Variable protocols for MR imaging of the breast exist. However, technical standards have been set by the ACR for proper imaging, interpretation, and accreditation (4,5). MR imaging of the breast should be performed with a dedicated breast coil, using at least 1.5 T magnet, and imaging parameters should be instituted to optimize high spatial and temporal resolution. MR imaging with 3 T magnet is evolving and slowly spreading; however, its advantage over the more commonly used 1.5 T magnets is not known yet.

Technical advances in breast MRI have led to improved sensitivity for the detection of invasive breast cancer, currently reported to range from 89% to 100% (6,7). Although previous studies in DCIS showed low and variable sensitivities, with improved techniques, contemporary studies report higher sensitivity of up to 89% with a range of sensitivity between 60% and 100% (8,9,10). In that regard, MRI is superior to mammography

in delineating DCIS extent (10). Moreover, recent advances introduced the use of CAD in interpretation of breast MRI. This technology uses special software analysis of the lesion kinetics and performs post processing of the images, therefore, allowing the radiologist to determine the kinetic curve type. Some data suggest that CAD may improve discrimination between benign and malignant masses (11); however, a metaanalysis by Dorrius et al. showed little added value for experienced radiologists and may be more helpful for less-experienced readers (12).

Breast MR lesion characterization and assessment is based on the ACR BIRADS MR lexicon which incorporates terminology and specific descriptors of breast MRI findings, in addition to assigning a final BIRADS category in the assessment, similar to mammography. By definition, an enhancing focus is less than 5 mm. A mass is a space-occupying lesion, 5 mm or more in size. Non-mass-like enhancement (NMLE) can be clumped foci or ductal enhancement. Masses are evaluated based on shape, margin characteristics, internal enhancement, and kinetic analysis. To mention some descriptors of malignancy, an irregular mass, spiculated margins, heterogeneous/rim enhancement, and rapid wash-in and wash-out kinetics are characteristic of malignancy (Fig. 28.1). NMLE, which is more typical of DCIS, can be focal, linear, or ductal enhancement in a ductal or segmental distribution (Fig. 28.2) (13). As such, analysis of breast MR enhancing lesions involves analyzing both lesion morphology and kinetics of enhancement to provide the most specificity in lesion characterization (14).

Screening Breast MRI

Breast MRI is a validated screening modality in addition to mammography in patients at high risk for breast cancer, and the combination of the two screening tests has been shown to be the most accurate way to detect breast cancer in these patients (15). Cancer yield achieved by MRI alone was significantly higher compared to the yield from mammography or US in a prospective multicenter cohort trial by Kuhl et al. (16). In a study by Morris et al., mammographically occult breast cancer was detected by screening breast MRI in 4% of high-risk women, with a positive predictive value (PPV) of 24% (17). For women with *BRCA1* gene mutations, MRI is a very sensitive screening tool when used in conjunction with mammography. In a multicenter multimodality prospective trial by Sardanelli et al., which looked at screening in women with genetic-familial risk for breast cancer, MRI sensitivity of 94% and PPV of 63% were found (18). Many studies confirm that breast MRI is a validated

FIGURE 28.1 Normal breast lobules. Three terminal duct-lobular units are surrounded by adipose and fibrous tissue.

FIGURE 28.2 Normal breast lobule. The presence of myoepithelial cells is illustrated by positive staining for smooth muscle myosin heavy chain.

screening tool in selective women at high risk for breast cancer (19–22).

In 2007, the ACS published new guidelines for high-risk screening with MRI based on scientific evidence and expert opinion (Table 28.4) (23). According to these new guidelines, high risk is defined as a lifetime risk of 20% to 25% or more, *BRCA* gene mutation carrier or first-degree relative of *BRCA* carrier, women treated at early age with chest radiation, and hereditary syndromes that place women at high risk for breast cancer. Currently, not enough data exist to support or refute annual breast MRI in women with a personal history of breast cancer or with high-risk lesions, and these patients are to be assessed on a case-to-case basis.

Breast MRI also serves to screen the contralateral breast in women with recently diagnosed breast cancer. A recent multicenter prospective trial evaluating contralateral breast cancer in women with recently proven breast cancer found clinically and mammographically occult breast cancer in 3.1% of 969 women, with a sensitivity of 91% and a negative predictive value (NPV) of 99% (24).

Diagnostic Breast MRI

Preoperative Evaluation of Breast Cancer

There are several clinical scenarios in which breast MRI is useful in addition to mammography, with the most common indication being preoperative staging of a newly diagnosed invasive cancer or DCIS. Breast MRI can delineate clinically and mammographically occult additional disease, including *in situ* disease associated with invasive cancer, and can detect non-calcified DCIS. In that regard, MRI is superior to mammography or US in defining local extent of the disease and can identify additional sites of disease in 14% to 27% (25). Liberman et al. found that 48% of women who underwent preoperative MRI of the breast had additional foci of disease unsuspected by mammography (26). In a study by Girardi et al. additional mammographically occult cancer was detected in 9% of patients staged with MRI preoperatively (27). As such, the addition of breast MRI can aid in surgical planning, including decisions regarding the role of mastectomy or the consideration for neoadjuvant chemotherapy. In one study by Braun et al. looking at the influence of preoperative MRI on surgical management, clinical management was changed in 27.5% of patients (28). It is advisable to biopsy additional suspicious foci detected by MRI

Table 28.4 Indications for Annual Breast MRI Screening in Association with Mammography**Evidence-Based Recommendations:**Confirmed *BRCA* mutation carrier statusUntested but with first-degree relative with positive *BRCA* mutation status

Estimated lifetime risk of developing disease >20% (based on risk models)

Expert Opinion:*Recommended*

Prior radiotherapy to the chest wall (between ages 10 and 30)

Patients (and first-degree relatives) with predisposing cancer syndromes:

Li-Fraumeni Syndrome

Cowden Syndrome

Bannayan-Riley-Ruvacalba Syndrome

No recommendation (for or against)

Estimated lifetime risk 15% to <20% (based on risk models)

Lobular proliferative disease (LCIS or ALH)

Atypical ductal hyperplasia

Mammographic heterogeneity or density

Women with personal history of breast cancer (including DCIS)

Not recommended

Estimated lifetime risk <15%

 LCIS, lobular carcinoma *in situ*; ALH, atypical lobular hyperplasia; DCIS, ductal carcinoma *in situ*

to avoid overestimation of disease and unnecessary mastectomy. With that in mind, the debate over the usefulness of MRI preoperatively continues. Opponents of MRI staging consider that additional foci of disease are treated with radiation and that the MRI-detected cancers may not be biologically important. Following the European Comparative Effectiveness of MRI in Breast Cancer (COMICE) trial published in 2010, which concluded that MRI did not decrease surgical negative margins and led to unnecessary mastectomies, selective patients are referred for preoperative MRI, and many others are not being staged with MRI. Preoperative MRI should still be considered in women less than 50 years of age, in women with dense breasts, and with histological diagnosis of invasive lobular cancer. The effect of MRI staging on patient mortality outcome is still unknown. To date, breast MRI remains the most accurate tool to delineate extent of disease of breast cancer; however, radiologists have to be aware that additional multicentric foci may not necessarily validate mastectomy as most foci may be treated by radiation. Additional studies are needed to elucidate outcome of patients in terms of recurrence and mortality.

MRI is not the best test for the exclusion of malignancy in the work-up of mammographic calcifications or other mammographic abnormality, and suspicious findings should undergo core biopsy. A helpful role of MRI in such clinical scenarios would be to delineate the extent of disease and to rule out an underlying occult invasive component. For women presenting

with suspicious clinical findings for breast cancer and negative conventional imaging tests, MRI of the breast has an added value. These instances include a woman with a palpable suspicious mass, women with metastatic axillary lymph nodes but no mammographically defined breast primary cancer, and those with pathological unilateral nipple discharge or Paget's disease, and a negative mammogram and US.

MRI: Other Indications

In patients presenting with an increasing mammographic density at the lumpectomy site following breast-conserving therapy (BCT), MRI is better than mammography or US for recurrent disease with high specificity and NPV. In addition, MRI has a role in determining the response to neoadjuvant chemotherapy, and it is more reliable than mammography or US in that respect. However, while MRI may not show residual enhancement following chemotherapy, it is not 100% accurate in the detection of residual disease, and a 23% risk of underestimation has been reported (29).

MRI-Guided Core Biopsy

MR evaluation of the breast should not be offered as a service without the capability for MRI-guided breast biopsy. The procedure is performed for MRI-only detected suspicious abnormalities which do not have a correlate on conventional imaging. MR biopsy procedure has been widely applied in Europe and the United States, and is an accurate and safe test with an NPV of 93% and PPV of 100% (30). The outcome of positive MR breast biopsy has been evaluated, with a trend towards DCIS in most positive biopsies found across several studies. Upgrade rates of DCIS to invasive cancer of 17% were found by Lee et al. (31) and of ADH to cancer in up to 38% (32,33). Therefore, pathology and imaging correlation by the radiologist is key to the management recommendation of a biopsied lesion with MRI.

BREAST PATHOLOGY

The breast is a modified sweat gland composed of 2 components: the large ducts and the TDLU, surrounded by adipose and fibrous tissue. The large duct system of subsegmental, segmental, and lactiferous ducts converge and empty onto the nipple. The TDLU is the most distal part of this branching ductal system. It is connected to the subsegmental ducts and represents the secretory unit of the gland (Fig. 28.1). Normal ducts and lobules are lined by a single layer of epithelium with an underlying layer of myoepithelial cells (Fig. 28.2). The TDLU is felt to be the site of origin of most pathologic entities of the breast, including fibrocystic changes, ductal hyperplasias and the majority of carcinomas (16).

Fibrocystic Changes

The breast ducts and lobules can show a wide range of benign nonproliferative and proliferative epithelial lesions. Nonproliferative lesions include cysts (macroscopic and microscopic), duct ectasia, fibrosis, and apocrine metaplasia. Proliferative lesions were first separated into different risk categories based on the work of Dupont and Page (NEJM, 1985). Patterns associated with a mildly increased risk (~two-fold) of subsequent breast carcinoma are considered proliferative changes, and include usual ductal epithelial hyperplasia (Fig. 28.3), lobular hyperplasia, sclerosing adenosis, radial scars, and intraductal papillomas (25). Both sclerosing adenosis and radial scars (Figs. 28.4 and 28.5) show distortion of normal breast architecture, and

FIGURE 28.3. Usual ductal hyperplasia. Slightly expanded ducts are filled with hyperplastic ductal epithelial cells and myoepithelial cells in an irregular fenestrated growth pattern.

FIGURE 28.5. Radial scar: A stellate lesion with irregular ducts radiating from the elastotic center; the entrapped glands may mimic an invasive ductal carcinoma.

this irregular gland pattern may mimic an invasive carcinoma. These benign proliferations maintain a normal myoepithelial cell layer, which can be highlighted by immunohistochemical stains. Intraductal papillomas have fibrovascular cores lined by myoepithelial cells and one or more layers of epithelial cells (Fig. 28.6). Papillomas involving large ducts near the nipple may cause a bloody nipple discharge.

Atypical ductal hyperplasia (ADH) and atypical lobular hyperplasia (ALH) are associated with a higher increased risk of subsequent breast cancer, about five-fold in most studies (25). ADH is characterized by architectural patterns approaching that of *in situ* carcinoma, while ALH shows expansion of the lobule by a loose, monomorphic cell population (Figs. 28.7 and 28.8). Reproducibility of the diagnosis of ADH is still problematic, but more uniform criteria are now used by most pathologists (26). There is still controversy as to whether size criteria should be used to separate ADH from low-grade DCIS (2 completely involved ducts or 2 mm). Excision is recommended for ADH found on core biopsy, as up to 30% of cases will have carcinoma (*in situ* or invasive) found on evaluation of the surrounding tissue (27). ADH can also involve a radial scar or intraductal papilloma.

A newly appreciated group of lesions are columnar cell change, columnar cell hyperplasia, and flat epithelial atypia (Figs. 28.9 and 28.10). These lesions were originally described by Azzopardi (ref 431, added to the end of the ref list) and their significance has been reappraised due to their frequent association with mammographically detected microcalcifications (28). More recently, it has been noted that flat epithelial atypia (Fig. 28.11) has a high association with low-grade DCIS (29) and invasive tubular carcinoma (30). Molecular studies may be able to further characterize these lesions and their role in breast carcinogenesis. Currently, excision is recommended for any of these atypical lesions identified on needle core biopsy.

In Situ Carcinoma

Ductal Carcinoma In Situ

DCIS, or intraductal carcinoma, is a heterogeneous group of lesions with the proliferation of malignant cells confined within the ductal system. Traditionally, DCIS was classified on the basis of its architectural pattern, often dichotomized as comedo and

FIGURE 28.4. Sclerosing adenosis. A well-developed lobulocentric distribution of dilated ducts and overgrowth of spindly myoepithelial cells may be mistaken as malignancy in core biopsy or frozen section.

FIGURE 28.6. Intraductal Papilloma. A well-circumscribed papillary proliferation fills a dilated duct. The presence of fibrovascular core of the papillae indicates benignity.

FIGURE 28.7. Atypical ductal hyperplasia. The proliferation has a cribriform growth pattern approaching that of a ductal carcinoma *in situ*, but the microlumens are more irregular in sizes and shapes.

noncomedo types. Noncomedo patterns include solid, cribriform, micropapillary, clinging, and papillary types. Combinations of these patterns are not uncommon in a biopsy. Several grading schemes incorporating both architectural and nuclear features have been proposed, but the Holland version, where nuclear features predominate, was most reproducible in one study (31,32). The presence of intraluminal necrosis and calcifications is usually noted, along with the nuclear grade and pattern(s).

Comedo-type DCIS (comedocarcinoma) shows a solid proliferation of large, pleomorphic nuclear grade 3 epithelial cells, with numerous mitoses and central necrosis containing cellular debris, so-called “comedo-necrosis” (Fig. 28.12). The necrotic material often becomes calcified, and these coarse calcifications have a distinctive mammographic appearance outlining the ductal system (“casting calcifications”). Periductal fibrosis and inflammation is common in comedo-type DCIS and can be a diagnostic problem, as microinvasion is a feature more frequently associated with comedo-type DCIS than other patterns (33,34). Extension of the large pleomorphic cells into the distal lobular unit is a pattern known as “cancerization of lobules.”

The solid, cribriform, papillary, and micropapillary patterns of noncomedo DCIS are usually composed of uniform low-grade or intermediate-grade nuclei. Cribriform patterns show smooth, rounded, “punched-out” spaces (Fig. 28.13). The micropapillary

FIGURE 28.9. Columnar cell change with microcalcifications.

subtype does not contain fibrovascular cores, whereas papillary DCIS does (Fig. 28.14). The “clinging” or “flat” type of DCIS may have either low- or high-grade nuclei. Microcalcifications may be associated with these noncomedo patterns and may be detected by mammography. Their pattern of distribution is less specific than that of the comedo DCIS and may be similar to that seen in benign conditions.

DCIS is currently treated by wide local excision or mastectomy, similar to invasive carcinoma. Breast conservation is typically followed by radiation. Margin status and size of the lesion appear to be significant factors related to risk of recurrence (35,36). Silverstein et al. (37) created the Van Nuys Prognostic Index (VNPI) by combining pathologic classification (non-high-grade nuclei without necrosis; non-high-grade nuclei with necrosis; high-grade nuclei), tumor size, and closest margin width. The VNPI score, by combining these features (range, 3 to 9) stratifies the risk of local recurrence after breast-conserving surgery (BCS). Lesion size is often problematic by pathologic evaluation, as most DCIS is not grossly evident. It is not practical to submit all tissue from an excisional biopsy for microscopic evaluation, so sectioning is guided by the type of lesion and radiographic findings. Mammography can often give a more accurate size of the lesion, but only in tumors that are entirely marked by calcifications. Margin width is most easily measured microscopically

FIGURE 28.8. Atypical lobular hyperplasia. The lobular glands are somewhat expanded, with a loose monomorphic cell population.

FIGURE 28.10. Columnar cell hyperplasia.

FIGURE 28.11. Flat epithelial hyperplasia. This is a columnar lesion characterized by mildly atypical epithelial cells, which may represent a precursor of or the earliest morphologically recognizable form of low-grade ductal carcinoma *in situ*.

FIGURE 28.13. Cribriform ductal carcinoma *in situ*. Expanded duct is filled with low- to intermediate-grade neoplastic cells forming secondary rigid cribriform microlumens.

in perpendicular sections, which requires the presence of colored inks for unique identification of each margin.

Paget's Disease of the Nipple

Paget's disease of the nipple reflects direct extension of DCIS, usually high grade, into the lactiferous ducts and adjacent skin. Clinically, the nipple appears excoriated. The DCIS may or may not be accompanied by invasive carcinoma. Histologically, the Paget cells are large round cells with prominent nucleoli and pale cytoplasm. They occur singly within the layers of the epidermis, or may form groups at the dermal-epidermal junction, mimicking malignant melanoma (Fig. 28.15). Lesional cells of Paget's disease are positive for carcinoembryonic antigen (CEA) or cytokeratin 7 (CK7), and negative for Melan-A and HMB-45 (Fig. 28.16). Treatment is dictated by whether the underlying tumor is *in situ* or invasive.

Lobular Carcinoma *In Situ*

Lobular carcinoma *in situ* (LCIS) was first described by Foote and Stewart in 1941 and has been an enigma ever since. It is a multicentric lesion, with no identifying features on gross or

radiographic evaluation, and is often found as an incidental finding in biopsies performed for another reason. Histologically, in classic LCIS, the lobule is distended by a monomorphic population of small uniform cells with round nuclei and scant cytoplasm (Fig. 28.17). The cells may extend into the adjacent duct, growing beneath the normal ductal epithelium, a pattern known as “pagetoid spread.” There is continuing controversy as to whether LCIS is an obligate precursor of invasive lobular carcinoma, or just a marker of overall increased cancer risk in either breast (38). Certainly, LCIS is often found adjacent to invasive lobular carcinoma. The term “lobular neoplasia” is often used to encompass both LCIS and ALH, which have identical cytologic features, but minor differences in architecture. Recent studies suggest that the diagnosis of either LCIS or ALH on a needle core biopsy should lead to a surgical excision, with 14% to 38% of patients found to have a carcinoma, either DCIS, invasive ductal carcinoma, or invasive lobular carcinoma (27,39,40).

Pleomorphic Lobular Carcinoma *In Situ*

This pattern of *in situ* disease involves larger ducts and mimics the solid pattern of DCIS (41). The cells are evenly spaced,

FIGURE 28.12. Comedo-type ductal carcinoma *in situ*. Markedly expanded ducts are filled with high-grade neoplastic ductal cells with central necrosis and calcifications.

FIGURE 28.14. Micropapillary ductal carcinoma *in situ*. Low-grade neoplastic ductal cells form papillary fronds in an expanded duct. The papillary fronds lack fibrovascular core.

FIGURE 28.15. Paget's disease. Large, round, pale neoplastic cells occur singly within the epidermis, mimicking malignant melanoma.

slightly dyscohesive and may have visible intracytoplasmic lumina (Fig. 28.18). Immunohistochemistry for E-cadherin demonstrates loss of this membrane protein (Fig. 28.19). Treatment should be similar to DCIS, as this pattern of LCIS is considered a precursor lesion of invasive carcinoma, rather than just a risk factor for subsequent disease (42).

Invasive Carcinoma

Invasive carcinoma of the breast is defined by the presence of stromal invasion, usually manifest by a fibrotic, desmoplastic stromal reaction around the invading cells. Tumor may be microinvasive (<1 mm) within an area of DCIS, or may form an obvious tumor mass, clinically or radiographically. Tumors are classified by the pattern of growth into ductal and lobular forms. Breast carcinoma is surgically staged using the AJCC staging system based on the size of the invasive component. Synoptic checklist reporting using templates devised by the College of American Pathologists aids in ensuring that all-important pathologic features are documented. DCIS may be focally present adjacent to the invasive component or intermixed with invasive tumor. The term “EIC” denotes a tumor with an

FIGURE 28.16. Paget's disease. Paget's disease cells are positive for CEA or CK7, and negative for Melan-A and HMB-45.

FIGURE 28.17. Lobular carcinoma *in situ*. An expanded lobule is markedly distended by a monomorphic population of small uniform cells. The underlying lobular architecture is still recognizable.

extensive *in situ* component, defined as at least 25% of the tumor mass.

Invasive Ductal Carcinoma

The majority of invasive tumors of the breast are ductal and have varying morphologic patterns that have led to several subclassifications. Most of the special types listed below are distinguished because they have an extremely good prognosis. The majority of tumors (~75%) have no specific features and are designated carcinoma, not otherwise specified (NOS), or carcinoma of no special type (NST). These tumors may be composed of small glands, tubules, solid cords, or nests of cells with varying degrees of cytologic atypia surrounded by a reactive (desmoplastic) fibrous stroma (Fig. 28.20). The recommended grading system is the Nottingham modification of the Bloom-Richardson system, which is based on adding scores for architectural pattern, nuclear pleomorphism and mitotic count (43) (Table 28.5). Grade 1 tumors (well differentiated) have 3 to 5 points, Grade 2 tumors (moderately differentiated) have 6 to 7 points and Grade 3 tumors (poorly differentiated) have 8 to 9 points. While initially applied only to invasive ductal carcinoma, this system can also be applied to invasive lobular carcinomas and has been validated in numerous studies (44).

FIGURE 28.18. Pleomorphic lobular carcinoma *in situ*. This pattern of lobular carcinoma *in situ* involves larger ducts with evenly spaced and slightly dyscohesive tumor cells, mimicking solid pattern of ductal carcinoma *in situ*.

FIGURE 28.19. Lobular carcinoma *in situ*. Loss of E-cadherin staining of lobular carcinoma *in situ* in contrast with adjacent normal ducts with positive staining.

Special Types

Mucinous Carcinoma

Mucinous (or colloid) carcinoma usually occurs in postmenopausal women. The tumor is well circumscribed and may have a gelatinous gross appearance. Microscopically, nests of uniform small cells are surrounded by pools of mucin (Fig. 28.21). The *in situ* component is minimal, but may also show intraductal mucin production. Pure mucinous tumors are low grade and have an excellent prognosis with a low rate of lymph node metastasis (45). This is not true, however, of mixed carcinomas with a prominent nonmucinous, usual invasive ductal carcinoma component.

Tubular Carcinoma

Tubular carcinoma is a well-differentiated invasive carcinoma composed of small glands or tubules that can be difficult to distinguish from some benign lesions, especially radial scars. The tubules are arranged haphazardly, often with a surrounding cellular stroma. They are somewhat angular with open lumens

FIGURE 28.20. Invasive ductal carcinoma. Small solid cords of neoplastic cells with moderate to severe cytologic atypia are surrounded by a fibrous stroma.

Table 28.5 Modified Bloom-Richardson Grading Scheme

	Score

and are lined by a single layer of monomorphic epithelial cells (Fig. 28.22). Myoepithelial cells are absent, and immunohistochemistry for myoepithelial markers (smooth-muscle myosin heavy chain, calponin, p63, and/or CD10) is helpful in confirming the diagnosis on needle biopsy. In order to have an excellent prognosis, the tumor must be composed of at least 75% tubules and have grade 1 nuclei (46). Invasive tubular carcinoma is often associated with a low-grade micropapillary or cribriform DCIS or adjacent atypical columnar cell lesions (30). Tubular carcinomas are small, usually less than 1 cm, and are frequently detected by screening mammography. Tumors with a component of usual invasive ductal carcinoma should not be included in this category. Invasive cribriform carcinoma, which also has a good prognosis, may be mixed with tubular carcinoma.

FIGURE 28.21. Mucinous carcinoma. Nests of low-grade neoplastic cells in a cribriform pattern are surrounded by a large pool of mucin.

FIGURE 28.22. Tubular carcinoma. Well-formed angular, oval, and tubular glands with a single layer of neoplastic ductal cells diffusely infiltrate a desmoplastic fibrous stroma.

Medullary Carcinoma

Medullary carcinomas occur more commonly in women under 50 years of age and have a higher frequency in *BRCA1* mutation carriers. Clinically, the tumor is well circumscribed and may mimic a fibroadenoma. Microscopically, the tumor is composed of solid syncytial sheets of large anaplastic cells with pleomorphic nuclei, prominent nucleoli, and abundant mitotics (Fig. 28.23). Gland formation is absent. The tumor has a pushing border and is surrounded by a dense lymphoplasmacytic infiltrate. Only tumors with this strict morphology and no component of typical invasive ductal carcinoma have a good prognosis.

Micropapillary Carcinoma

Micropapillary carcinoma is a recently described entity with a characteristic morphology, high incidence of positive nodes at presentation despite small tumor size, and poor OS (47,48). The tumor is composed of small clusters of malignant cells floating within small clear spaces resembling lymphatic channels (Fig. 28.24). Most tumors have high nuclear grade and true

FIGURE 28.24. Invasive micropapillary carcinoma. Small clusters of intermediate-grade neoplastic cells lie within small clear spaces of a fibrocollagenous stroma mimicking tumor cells in lymphatic spaces.

lymphatic space invasion. A component of usual invasive ductal carcinoma may be present.

Papillary Carcinoma

Papillary carcinoma is a rare subtype. Several different entities are encompassed within this terminology. Solid papillary carcinoma and encapsulated (intracystic or encysted) papillary carcinoma have indolent behavior like a DCIS, although they lack surrounding myoepithelial cells (49,50) (Fig. 28.25). Encapsulated papillary carcinoma forms a well-circumscribed mass and may have DCIS present in adjacent ducts. Invasive papillary carcinomas have evidence of destructive stromal invasion adjacent to larger solid nests.

Inflammatory Carcinoma

The term “inflammatory carcinoma” originated as a clinical term to describe a patient presenting with a reddened edematous breast suggesting mastitis. Skin biopsies from such patients often show tumor thrombi in dermal lymphatic channels (Fig. 28.26), but this is not true in every case.

FIGURE 28.23. Medullary carcinoma. Highly pleomorphic neoplastic cells in a syncytial pattern are surrounded by a diffuse lymphocytic infiltrate.

FIGURE 28.25. Solid or intracystic papillary carcinoma. Low power shows a well-circumscribed tumor with branching network of fibrovascular stroma. A cystic formation is not necessary for the diagnosis.

FIGURE 28.26. Inflammatory carcinoma. Carcinomatous emboli are present in dilated dermal lymphatics.

FIGURE 28.28. Invasive lobular carcinoma. Tumor cells infiltrate in a concentric pattern around a normal duct.

Invasive Lobular Carcinoma

Invasive lobular carcinoma comprises about 10% of all breast cancers. The classic form of invasive lobular carcinoma is composed of small monotonous tumor cells with scant cytoplasm growing in linear columns ("Indian file") or in concentric ("targetoid") patterns around normal ducts and lobules (Figs. 28.27 and 28.28). A mild stromal desmoplastic reaction may be present around the tumor cells, but many invasive lobular carcinomas do not form a discrete tumor mass. This diffuse growth pattern can be a problem when attempting conservative surgical excision, and tumors are frequently upstaged after surgery (51).

Variant forms of invasive lobular carcinoma include alveolar, solid, and trabecular patterns composed of the same monomorphic small cells. Signet ring cell carcinoma (Fig. 28.29), in which the cells contain prominent intracytoplasmic vacuoles, is considered a variant of invasive lobular carcinoma due to its similar growth patterns. Another variant is pleomorphic lobular carcinoma, where the columns of cells show marked nuclear atypia.

Stage for stage, the prognosis of patients with invasive lobular carcinoma is no different from invasive ductal carcinoma. However, the patterns of metastatic disease are different, with lobular carcinomas having a propensity to metastasize to the

meninges, and peritoneal and pleural surfaces. Invasive lobular carcinomas, and mixed lobular and ductal invasive carcinomas appear to be more frequent in postmenopausal women taking combination hormone replacement therapy (52).

Tubulo-lobular Carcinoma

This tumor shows a mixture of invasive lobular and tubular carcinoma growth patterns with low-grade nuclei. The mixed architectural pattern parallels the expression of markers of ductal and lobular differentiation, and these tumors appear to have a good prognosis.

Other Tumors

Metaplastic Carcinoma

The term "metaplastic carcinoma" is used to describe tumors with prominent morphologic patterns different from usual ductal and lobular patterns. The term encompasses epithelial tumors (carcinomas) showing squamous cell differentiation, monophasic spindle cell carcinoma, and biphasic tumors with both epithelial and mesenchymal elements (Fig. 28.30). Spindle

FIGURE 28.27. Invasive lobular carcinoma. Small monotonous tumor cells invade in linear "Indian file" pattern.

FIGURE 28.29. Signet ring cell carcinoma. Tumor cells contain large amounts of intracytoplasmic mucin, which pushes the nuclei to the cell periphery, thus resembling signet rings.

FIGURE 28.30. Metaplastic carcinoma. The area to the right of this poorly differentiated invasive breast carcinoma shows squamous differentiation.

cell (sarcomatoid) carcinomas express epithelial markers (cytokeratins) despite their spindle cell morphology and are aggressive tumors with a high rate of extranodal metastases. Biphasic tumors (biphasic sarcomatoid carcinoma or carcinosarcoma) may contain heterologous elements, such as malignant cartilage or bone (Fig. 28.31). These are also aggressive tumors that tend to metastasize as well as recur (53).

Phyllodes Tumors

Phyllodes tumors, formerly known as “cystosarcoma phyllodes,” are biphasic tumors similar to fibroadenomas with a spectrum of morphology and biologic behavior. The median age is 45 years, which is several decades higher than for fibroadenoma. These tumors are grossly well circumscribed, but are infiltrative on microscopic examination. They are composed of benign glandular elements with a prominent stromal component showing varying degrees of hypercellularity, nuclear atypia, and mitotic activity (Fig. 28.32). The older term “cystosarcoma phyllodes” refers to the leaf-like architectural pattern with intervening cystic spaces. While features such as

FIGURE 28.31. Metaplastic carcinoma. A well-developed cartilaginous focus is seen in this poorly differentiated invasive carcinoma with chondroid differentiation.

FIGURE 28.32. Phyllodes tumor: Phyllodes tumors have leaf-like architectural pattern with intervening cystic spaces. They are composed of benign glandular elements with a prominent stroma showing varying degrees of hypercellularity, nuclear atypia, and mitotic activity.

size, mitotic activity, and cellular atypia correlate with clinical behavior, attempts to reliably divide these tumors into benign and malignant forms are not always successful. The lower grade tumors tend to recur, especially if incompletely excised due to the subtle infiltrative margin. Obvious malignant tumors may have stromal overgrowth, which portends a worse prognosis (54,55). Overall, lymph node metastases are uncommon and surgery is the primary treatment.

Angiosarcoma

Angiosarcoma is the most common primary sarcoma of the breast and may be associated with previous radiation therapy. The tumors are composed of anastomosing vascular channels lined by endothelial cells, which range from mildly atypical to frankly malignant. The distinction between a benign angiosarcoma and a low-grade angiosarcoma can be difficult on a small biopsy. Overall 5-year survival is around 60% with multimodality therapy (56,57). Other histologic patterns of primary breast sarcoma also occur.

CLASSIFICATION OF BREAST CANCER

Estrogen interacting with nuclear estrogen receptors (ER) regulates cell growth, proliferation, and differentiation of normal breast epithelium, and those carcinomas that express ER. Measurement of ER in breast cancers is performed in order to predict the response of an invasive tumor to endocrine therapy, or the benefit of hormonal therapy for risk reduction in cases of *in situ* carcinoma. Progesterone receptor (PR) is an ER-regulated gene product with similar prognostic implications. Hormone receptors can be measured biochemically by ligand binding assays, or by immunohistochemical (IHC) techniques using monoclonal antibodies directed against the receptor protein (Fig. 28.33). Correlation between the two techniques is high (58). With today's smaller tumors usually diagnosed by needle core biopsy, IHC is the preferred method of analysis. This method also allows distinction between invasive tumor, *in situ* tumor, and nontumor elements. The American Society of Clinical Oncology and College of American Pathologists recently published a joint guideline containing an algorithm for testing, interpretation, and reporting,

FIGURE 28.33. Positive estrogen receptor: More than 90% of tumor cells of this invasive ductal carcinoma are strongly positive for estrogen receptor.

as well as requirements for standardization and validation of testing techniques (59). Both the percentage of cells stained and the intensity of the staining should be reported. A positive result is defined as more than 1% of cell nuclei staining positive.

HER2/Neu

HER2/neu or c-erbB2 is an oncogene whose protein product is a membrane receptor tyrosine kinase. Amplification of *HER2/neu* is seen in most cases of comedo-type DCIS and in about 20% to 30% of invasive ductal carcinoma, usually of high grade. It can be detected by immunohistochemistry for the protein product or by gene amplification techniques, such as fluorescence *in situ* hybridization (FISH) or chromogenic *in situ* hybridization (CISH). Increased copy number is closely associated with elevated protein expression. Amplification of *HER2/neu* identifies a subset of patients with a poor prognosis who benefit from treatment with trastuzumab, a monoclonal antibody directed against the *HER2/neu* receptor (60,61). The American Society of Clinical Oncology and College of American Pathologists published a joint guideline containing an algorithm for testing, interpretation and reporting, as well as requirements for standardization and validation of testing techniques (62). A positive *HER2/neu* result is 3+ IHC staining, defined as uniform intense membrane

FIGURE 28.34. Positive *HER2/neu*. Strong (3+) *HER2/neu* membrane immunoreactivity is seen in this invasive ductal carcinoma.

FIGURE 28.35. Amplification of *HER2/neu* gene (red dots) by fluorescence *in situ* hybridization.

staining of greater than 30% of invasive tumor cells (Fig. 28.34) or a FISH result of more than 6 *HER2* gene copies per nucleus OR a FISH ratio (*HER2* signals to chromosome 17 signals) of more than 2.2 (Fig. 28.35). Implementation of these guidelines will result in more reproducible results between laboratories.

Triple Negative Tumors

A subset of breast carcinomas is negative for the usual markers ER, PR, and *HER2/neu*. These tumors express cytokeratin 5/6, which denotes a basal phenotype, in contrast to the luminal cell phenotype of most breast carcinomas (63,64). These tumors typically are high grade with a central hyalinized scar or necrosis (65), occur in younger women, and are associated with poor survival (66). Many metaplastic carcinomas fall into this group of tumors. Most triple negative tumors are positive for epidermal growth factor receptor (EGFR), which may provide a target for future therapy (63).

BRCA1 and BRCA2

Histologically, tumors associated with either *BRCA1* or *BRCA2* are typically invasive ductal carcinomas. *BRCA1*-mutation associated breast cancers are usually triple negative and express basal markers (67). This is in contrast to *BRCA2*-mutation associated tumors, which are usually ER positive (ER+) and express a luminal A phenotype (44).

Other Markers

Proliferation rate measured by flow cytometry (S-phase fraction), DNA image cytometry, or IHC (Ki67 MIB-1 antibody) has a relation to clinical outcome (68). However, these and other markers suffer from problems with standardization of results between laboratories. A recent working group has addressed Ki67 assessment (69). Newer techniques using protein or gene microarrays to identify putative markers are more exciting. One panel of 22 genes has been used to predict the likelihood of recurrence in ER+ node-negative tumors (70).

Molecular Profile of Breast Cancer

Based on the results of microarray analysis, breast cancers can be broadly classified into 5 subgroups: luminal A, luminal B,

normal breast-like, HER2-positive (HER2+), and basal-like. The molecular features have some correlate with histologic grade and expression of hormone receptors (71). While, in general, these different groups have different prognoses, the basal-like group is most heterogeneous, containing medullary carcinoma, metaplastic carcinoma, and rare tumor types, such as adenoid cystic carcinoma (72).

GENERAL MANAGEMENT OF BREAST CANCER—SURGICAL CONSIDERATIONS

Historical Perspective

Early descriptions of breast disease date back to ancient Chinese and Egyptian civilizations, and those of breast malignancy date back to Hippocrates and Celsus. The predominating theories of Hippocrates and Galen's 4 bodily humours were taken as dogma until the 1700s, when LeDran proposed the revolutionary concept of lymphatic spread. Evolutions in surgical treatment of breast cancer, however, awaited the introduction of anesthesia and Listerian antiseptics.

Faced with a high incidence of local recurrence and the understanding that cancer growth and spread occurred in an "orderly sequential process," the radical mastectomy was championed as an attempt to get at "the roots" of the tumor. At the same time, surgeons suggested that the axillary nodes be removed as part of the operation on breast cancer, given the propensity of nodal involvement.

The earliest description of the mastectomy was by Jean Petit, but Charles Moore and Sir Joseph Lister are credited with advocating the more radical approach by incorporating the division of the pectoral muscles when performing a mastectomy, which allowed for improved exposure of the axillary contents. The subsequent ground work by Pancoast, Gross, and Moore of London lead to the reports of Willie Meyer and William Halsted, who simultaneously published papers advocating the systematic removal of nodes in continuity with the primary cancer in 1894 (73,74). These papers presented a systemically applied approach to the radical mastectomy and offered a standardized technique of lymphadenectomy in breast cancer in an anatomically logical and exact manner. Technically, the procedure involved an *en bloc* resection of the breast, the pectoralis major and minor, and a full axillary dissection, levels I to III. In so doing, the local recurrence rate dropped from nearly 50%–80%, to 6%, and the reported 3-year cure rate was 38.3% (75). So successful was this operation that it became the yardstick against which all other interventions would be measured. Even

with this breakthrough, Halsted recognized that node negativity did not ensure survival.

The extension of the operation was explored by surgeons in Europe and the U.S., including operations that involved resection of the supraclavicular nodes (Halsted) or the internal mammary nodes (Handey), and extension of surgery into the neck and/or mediastinum (Urban and Wangenstein) (76,77). However, these increasingly extensive surgeries did not improve OS, but did increase operative mortality, and thus, were largely abandoned. Simultaneously, Sir Geoffrey Keynes first described the role of radiation therapy (RT) in local control of cancer in 1930, and Robert McWhirter first demonstrated that axillary radiation was effective in locoregional control in breast cancer (78). This presaged the controversy regarding surgical resection versus radiotherapy for locoregional control and its relationship to survival.

Advances in medicine and public health between 1880 and the mid-1900s led to improvements in breast cancer detection and smaller tumors, which led surgeons to explore options beyond the radical mastectomy. It was not until the 1970s, however, that the surgical trend for breast cancer management was deliberately directed toward less-aggressive approaches (79).

Modern History

Over a decade after the first randomized clinical trial, evaluating the outcomes of breast conservation combined with postoperative radiation versus mastectomy, revealed no difference in either OS or in breast recurrence between treatment groups, the National Surgical Breast and Bowel Project (NSABP) launched a series of trials where the underlying construct was that breast cancer was systemic at origin and therefore, the technique of surgery was less important than systemic therapy. Under their dogma of "systemic disease controls survival," the group accepted negative margins delineated as "no tumor at ink," and this qualification would distinguish NSABP trials from other investigations. In total, 6 major prospective randomized trials were initiated between 1972 and 1983, and are summarized in Table 28.6.

The NSABP B-06 trial compared modified radical mastectomy to lumpectomy/axillary dissection with or without breast irradiation in 1,851 patients with stage I–II breast cancer (80). At 20 years of follow-up, there was no significant difference in either disease-free survival (DFS) or OS. Additionally, whole breast irradiation was found to reduce local recurrence in patients who received breast conservation. With these results, BCT was rightfully accepted as standard of care for nonmulticentric breast cancer. A similar trial was reported by Veronesi for the National Tumor Institute of Milan (81). Over 700

Table 28.6 Randomized Trials of Breast-Conserving Therapy and Mastectomy

Study	No. of Patients	Median Follow-up (years)	In-Breast Failure BCS + XRT Mastectomy		Overall Survival BCS + XRT Mastectomy	
IGR (83)	179	15	9%	14%	73%	65%
Milan (81)	701	20	9%	2%	42%	41%
NCI (84)	237	18	22%	6%	59%	58%
EORTC (85)	824	10	20%	12%	65%	66%
Danish (82)	904	6	3%	4%	79%	82%
NSABP B6 (7)	1219	20	14%	10%	46%	47%

women with tumors under 2 cm were randomized to mastectomy versus quadrantectomy with axillary dissection followed by radiotherapy. Adjuvant chemotherapy using cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) was administered to all patients with node-positive disease. With 20 years of follow-up, the actuarial DFS and OS were similar in both groups.

The Danish Cooperative group conducted a similar study of 895 patients and once more showed that with 6 years of follow-up, equivalent rates of local recurrence and OS were achieved (82). Finally, Arriagada et al. reported the results of a randomized trial involving 179 patients treated at the Institut Gustave-Roussy and once more demonstrating an equivalent DFS and OS (83). Notable studies from the NCI and EORTC showed a higher risk for local recurrences with breast conservation compared to mastectomy, but these studies were flawed for either inadequate margin assessment or frank margin involvement, respectively (84,85).

In the final analysis, the weight of evidence supports equivalence of BCT versus radical or modified radical mastectomy for early-stage breast cancer. The NSABP trials rigorously and systematically both challenged and advanced breast cancer surgical technique and systemic therapy. Ongoing debate about which patients were candidates for BCT continued for decades, ultimately landing at the determination based on the breast-tumor volume ratio, absence of multicentric disease, and eligibility for postlumpectomy radiation (86).

The NSABP applied similar methodology in evaluating the benefit of surgery and radiation in the management of ductal carcinoma *in situ* (DCIS). From the NSABP B-17 and B-24 trials, we learned that lumpectomy with radiation achieved the lowest rate of local recurrence but did not affect OS, and that tamoxifen could decrease not only ipsilateral recurrence but also contralateral new disease (87). NSABP B-32 compared axillary dissection to sentinel node biopsy in the management of the clinically negative axilla and demonstrated the success of sentinel node biopsy in predicting axillary involvement (88). Most recently, the American College of Surgeons Oncology Group Z-11 trial has suggested that verification of axillary involvement is adequate, and completion axillary dissection is not associated with improved survival in limited (1–2) node-positive disease.

In Situ Disease

In the past, DCIS was managed, like any breast cancer, by mastectomy. This was effective from a cancer point of view and resulted in a local recurrence rate of only 1% (89). Interestingly, at a time when breast-conservation surgery was being advocated for invasive breast cancer, total mastectomy was still the standard of care for DCIS. Current therapies have since evolved based on extrapolation of the trials of BCT with total mastectomy in invasive breast cancer, although there are no phase III studies comparing BCT with total mastectomy in DCIS.

Currently, most DCIS can be treated by wide local excision and radiotherapy. Margin status and size of the lesion appear to be significant factors related to risk of recurrence (35,36). Silverstein et al. created the VNPI by combining pathologic classification (non-high-grade nuclei without necrosis; non-high-grade nuclei with necrosis; high-grade nuclei), tumor size, and closest margin width (90). The VNPI score ranges from 4 to 12 and has been shown to stratify the risk of local recurrence after BCS, and has been used to identify a cohort where radiation may be safely omitted. However, the prospective randomized trial failed to validate a wide margin can be substituted for radiotherapy (91). Furthermore, both the NSABP and the EORTC trials demonstrated a 50% invasive component in the local recurrences in the nonradiated patients (92).

The indications for mastectomy for DCIS are: (1) persistent positive margins; (2) multicentric disease, that is, DCIS involving more than one quadrant; (3) cosmetically unacceptable breast-conservation surgery due to a large DCIS process in a comparatively small breast (93). For these cases, a total or skin-sparing mastectomy with sentinel lymph node biopsy is recommended. Sentinel node biopsy is performed to ensure the opportunity for lymphatic mapping will not have been sacrificed should occult invasive disease be identified on final pathology.

The role of sentinel node biopsy in DCIS treated with lumpectomy is less clear. Some have advocated for sentinel node biopsy in DCIS treated by lumpectomy when the diagnosis is based on a core needle biopsy since the risk of an invasive cancer at definitive excision ranges between 10% and 20%. In the largest series of sentinel node biopsy for pure DCIS, a 5% rate of nodal metastasis was described; however, 70% of these metastases were detected only by IHC staining (94). Others have suggested stratifying the risk of invasion based on retrospective studies, acknowledging that the implications of IHC positive nodes is unclear, especially in the context of known disease-specific survival from DCIS of 99% (95). Taking into account the published literature, consideration of lymphatic mapping is reasonable for a span of DCIS greater than 4 cm or a mass on mammography, palpable DCIS, high-grade DCIS, and in the presence or question of microinvasion (96).

Early Invasive Disease

Early invasive breast cancer is almost uniformly diagnosed by imaging modalities. While breast MRI has emerged as a valuable adjunct in the diagnostic evaluation of breast cancer, its widespread use as a screening tool has largely yet to be realized. Therefore, the majority of patients will present with lesions that have been identified by mammography.

Once the diagnosis of invasive cancer is established in early-stage disease, surgical planning commences. A thorough history, including family history, and physical examination is essential to establish both the patient's presentation and extent of clinically apparent disease, to screen for contraindications to BCT, classical multicentricity, or poor breast-tumor volume ratio, or contraindications to adjuvant radiation therapy, such as certain connective tissue disorders, pregnancy, or prior irradiation. Particular attention to the location of the tumor, its palpability, fixation to the skin or underlying chest wall, cutaneous changes, nipple irregularities, and regional nodal assessment are paramount. When there is a concern regarding family history, a referral to a genetic counselor for consultation regarding hereditary mutations is recommended.

Breast MRI has been employed in the evaluation of extent of disease with indeterminate success. While disease extent may be better delineated by MRI, and mammographically occult disease outside the operative field has been described (97), the only prospective randomized studies have failed to show any advantage to preoperative breast MRI, such as reduced positive margins, decreased local recurrence, or improved survival; yet an increased rate of unnecessary mastectomy due to false-positive MRI findings has been documented (98). However, the COMICE trial was underpowered, and the patients were across the full age and breast density spectrums. Furthermore, patients were taken to mastectomy with un-biopsied MRI findings. Prospective studies limited to the patients where MRI seems to realize the greatest benefit, the young with dense breasts, are unavailable.

Breast-conservation surgery should aim to resect the primary tumor with clear margins. This can be achieved either with the needle localization technique or one of the many other techniques that have been described in the literature to localize the lesion, such as intraoperative US localization or radioisotope guided resection (99,100). The ideal margin for breast cancer

in a wide local excision has been a well-published challenge; after all, an acceptable margin for one pathology may not be appropriate for another. In an recent review (101), Morrow references the exhaustive review of the technique and significance of the surgical margin for invasive breast cancer by Singletary, who analyzed 38 representative studies examining the impact of surgical margin on local recurrence (102). While it is difficult to discern a distinction between the significance of 1, 2, 3, or greater than 5 mm margins in patients with invasive breast cancer treated with whole breast irradiation with tumor bed boost, an increased local recurrence rate was demonstrated in patients with positive margins. Young age, large tumor size, positive lymph nodes, and the absence of systemic chemotherapy or endocrine therapy were identified as significant independent predictors of locoregional recurrence. The impact of the biology of the underlying cancer continues to be realized as research focuses on the impact of genomic analysis. The time-dependent nature of recurrence is further elaborated by Neuschatz et al. who showed that graded tumor-bed escalation in breast irradiation may establish equivalence in local recurrence for involved margins initially, but that after 5 years of follow-up, the local failure in the close/positive margin groups becomes apparent (103). While local failure was initially viewed as recoverable by mastectomy without impact on OS, the meta-analysis showed a survival disadvantage, with one mortality associated with every 4 recurrences at 15 years of follow-up (104).

Intraoperative margin analysis to ensure adequacy has been explored primarily using frozen section analysis, touch imprint cytology, or intraoperative imaging. A promising technique of treating potential positive margins is the use of intraoperative radiofrequency ablation, where a multipronged probe is deployed into the surrounding breast tissue at the completion of the lumpectomy before wound closure (105). Ablation is performed under US visualization for 15 minutes. Twenty-five percent of patients avoided returning for re-excision due to close margins evident on final pathologic analysis. However, longer follow-up is needed to ensure that the local recurrence remains low. A prospective randomized double-armed trial of the margin probe, a newer handheld device that utilizes radiofrequency signals to analyze the lumpectomy margin, reports a 56% reduction in re-excision with a positive margin rate of 5.6% in the probe group and 12.7% in the control arm (106).

Locally Advanced Breast Cancer

Locally advanced breast cancer is variously defined as primary tumor size greater than 3 to 5 cm, involvement of the chest wall, skin ulceration or satellitosis, and/or positive axillary nodes (107,108). Approximately 6% of breast cancers in the United States present as locally advanced breast cancer (LABC). These patients are candidates for neoadjuvant chemotherapy or endocrine therapy, which results in a higher rate of breast conservation, without a reduction in either DFS or OS (109). Additionally, neoadjuvant therapy has not been shown to increase the complication rate of surgery or delay the onset of further postoperative treatment. From a biological standpoint, neoadjuvant therapy provides the opportunity to assess the chemosensitivity of breast tumors *in vivo*. The use of neoadjuvant chemotherapy does result in a 30% and 40% decrease in the incidence of axillary nodal involvement, and up to a 20% complete response in responding patients (110–112). While neoadjuvant chemotherapy has not been shown to improve survival in LABC, it has demonstrated that up to 80% patients have significant breast tumor shrinkage, and only 2% to 3% will have progression of disease (108,109).

Approximately 25% of patients not candidates for breast conservation before treatment were able to conserve their breast after the administration of neoadjuvant chemotherapy. Data

from the NSABP B-18 trial demonstrated that patients who achieved a pathological complete response (pCR) have better survival than those who were partial responders (110). Kuerer et al. also demonstrated that the presence of residual disease in the axillary lymph nodes was a predictor of poor outcome and was associated with higher incidence of locoregional (14% vs. 5% in patients achieving a pCR in the nodes) and distant metastases (41 vs. 15%) (112). In this study, the eradication of nodal metastases was associated with improved survival. In addition, a pathologic complete response to neoadjuvant therapy has been more commonly noted in younger patients and in tumors that are ER negative (ER-), high-grade, ductal, and HER2/neu positive if treated with trastuzumab. Cancers with a high proportion of intraductal cancer and lobular carcinomas are also less likely to attain a complete pathologic response. Yet, the prognostic implications of failure to attain pCR do not seem to translate to the luminal A hormone positive and luminal B HER2/neu negative breast cancers (113). Neoadjuvant endocrine therapy has been used mainly in older women with ER+ disease; aromatase inhibitors are more effective than tamoxifen in inducing a local response but pCR is rare with endocrine therapy alone. The ACOSOG Z-1031 trial showed equivalent response rates to anastrozole, letrozole, and exemestane, with 51% patients with a planned mastectomy transitioning to breast conservation (114). A core biopsy of the breast is used to establish diagnosis and to obtain prognostic histologic features of the primary tumor. Multiple cores allow for staining for receptors and HER2/neu. A negative biopsy in the setting of a clinically suspicious or dominant breast mass should prompt additional work-up with open biopsy. If the patient could be a candidate for breast conservation with appropriate downstaging of tumor size, a microclip should be placed in the relevant breast tumor(s). This facilitates later identification of the cancer site in case of complete response to neoadjuvant therapy. Additionally, axillary evaluation establishes the nodal stage. For palpable disease, a needle biopsy can be performed, with either axillary US with needle biopsy or sentinel node biopsy being reserved for nonpalpable disease.

Nonetheless, clinical examination of the axilla remains unreliable, with reported false-negative examination in 21% to 42% of cases (110,115,116). Hence, other methods of accurately staging the axilla before initiation of treatment have been explored. US combined with physical examination has been shown to increase the reliability of axillary evaluation (117). Further, fine needle aspiration cytology of suspicious nodes, defined as size greater than 1 cm, loss of fatty hilum, cortical hypertrophy, and hypoechogenic parenchyma, has a reported sensitivity and specificity of 36% to 92%, and 69% to 100%, respectively (118–120). In a study of 103 cases of indeterminate or suspicious appearing lymph nodes from the University of Texas MD Anderson Cancer Center, only 11% node-positive patients were missed by US-guided cytology (120). All cases with 3 or more positive nodes, and 93% of cases where the size of the metastatic deposit was greater than 5 mm, could be identified by this technique. In this study, the overall sensitivity of ultrasound-guided fine needle aspiration (US-FNA) was 86%, specificity was 100%, PPV was 100%, and the NPV was 67%. Despite this, the false-negative rate of US-FNA remains 15% to 20% in the reported literature, and a major limitation of US remains the inability to detect metastases less than 5 mm in size. While the identification of node-positive disease by US-FNA can reduce the number of sentinel lymph node biopsy (SLNB) procedures by up to 15% and identify those patients who would not otherwise be candidates for neoadjuvant chemotherapy, sentinel node biopsy is still required in those patients who are node-negative based on US-FNA (119,121). Re-evaluation of the axilla after neoadjuvant therapy has also been reported in small studies to be predictive of axillary downstaging (117).

The timing of sentinel node biopsy in the US-FNA node-negative patient relative to chemotherapy remains controversial.

Small single-institution studies demonstrate the feasibility of lymphatic mapping subsequent to neoadjuvant chemotherapy, and the largest trial of 428 patients from the NSABP B-27 trial described a false-negative rate of 10.7% comparable to 9.8% in the NSABP B-32 trial of sentinel node biopsy in patients undergoing primary surgery (88). However, given the potential downstaging of the axilla, there remain concerns about establishing the extent of nodal involvement as patients with greater than 4 positive nodes will have alteration in radiation therapy field distribution. Chagpar et al. have attempted to develop a nomogram to assist in identifying those patients more likely to require extended field radiotherapy (122).

Even for patients with known node-positive disease the idea of delayed lymphatic mapping affords the opportunity for axillary downstaging. Preliminary studies had been promising, with a false-negative rate of 9.8% of sentinel node biopsy in patients with a known positive axillary node treated with neoadjuvant chemotherapy and subsequent lymphatic mapping (123). The prospective multicenter ACOSOG Z-1071 trial analyzing the success of lymphatic mapping in node-positive patients, proven by needle biopsy without excision, who have received neoadjuvant chemotherapy has completed accrual, and data are in analysis. All patients with LABC should undergo a baseline bone scan, and CT scans of the chest, abdomen, and pelvis since 30% of these patients would have metastatic disease (124). Patients are clinically assessed for response after 2 to 3 cycles, and radiological response can also be recorded at this time. If no response is present, a decision is made to continue with surgery if possible, or to change systemic therapy. Prior to surgical decisions being made, re-imaging of the breast should be performed as clinical examination alone is unreliable (125–128). Occasional patients will have residual microcalcifications or DCIS while the invasive cancer has a complete pathologic response (129). The contraindications for breast conservation after neoadjuvant chemotherapy are similar to those for primary BCT and include residual tumor >5 cm, skin edema or involvement, chest wall fixation, diffuse calcifications on postchemotherapy mammogram, multicentric disease, and contraindications to radiation therapy. As the risk of local recurrence after breast conservation in patients undergoing neoadjuvant therapy is slightly higher, the use of postmastectomy radiation in patients with larger cancers and persistently positive axillary nodes is recommended (109,130).

Immediate reconstruction in patients with LABC undergoing mastectomy has been shown to have a slightly higher rate of complications and result in a delay in treatment, as well as problems with cosmesis when postmastectomy radiation therapy is required. Given the multiple issues that are at play in the patient desiring immediate reconstruction, early consultations with both plastic surgery and radiation oncology should be performed, preferably before any surgery takes place.

Management of the Axilla

Although the clinical implications of axillary lymph nodal involvement has taken a varied course over the years, it still remains a major prognostic indicator of survival in breast cancer (131). Additionally, an axillary dissection remains of value in improving local control in patients with clinically positive axillae, though this has not translated into improved survival.

The largest prospective randomized trial evaluating the role of axillary lymphadenectomy was the NSABP-B04 trial (131). In this trial, 1,079 women underwent radical mastectomy including an axillary dissection, total mastectomy with axillary radiation, or total mastectomy alone. Of note, patients did not receive systemic therapy on study. The results showed an axillary recurrence rate of 5% in clinically node-negative patients treated with surgery or irradiation compared to 20% when the axilla was observed. However, there was no difference in the rate of

distant metastases or in survival in clinically node-negative breast cancer patients after 25 years. Most patients with axillary recurrence were salvaged by the performance of a delayed axillary dissection, whereas 1 patient had inoperable regional disease. This study thus demonstrated that leaving behind axillary nodes with metastatic disease had no significant impact on the overall outcome of the disease. A Danish randomized trial compared an extended radical mastectomy with nodal resection to total mastectomy with postoperative radiation, showing similar survival and suggesting that axillary radiation might be an acceptable alternative to surgical dissection of the axilla (132). In light of these data, the American College of Surgeons Oncology Group under Dr. Armando Giuliano designed the landmark Z-0011 trial opening in 1999 (133), the results of which have challenged the axillary management paradigm. In this revolutionary study, patients with T1–2 tumors with a clinically negative axilla undergoing BCT with radiation, and with 1 to 2 positive sentinel nodes identified at surgery, were randomized to axillary dissection, or no further surgery. Radiation to the axilla was disallowed. Patients were eligible regardless of age or receptor status. All received whole breast radiation, and 98% received adjuvant systemic therapy. The study failed to accrue well and closed with 931 patients. Yet with 6 years follow-up, the group reported an OS of 92%. There was no survival advantage from completion axillary dissection. The operative group had a 27% node-positive rate, and given the randomized nature of the study, it follows that the nondissected group also had a 27% rate of positive nodes left *in situ*. Yet there was no significant difference in local-regional recurrence (134). It is critical to realize in this study that all patients received whole breast radiation and the overwhelming majority received adjuvant systemic therapy.

A complete axillary dissection involves removal of the Level I to II nodal tissue from the axilla. This is defined as the space bounded by the pectoral muscles anteriorly, the latissimus dorsi muscle posteriorly, and axillary vein superiorly. The nerves to the latissimus dorsi and serratus anterior are preserved. If possible, the intercostobrachial nerve is also preserved to decrease the risk of arm paraesthesias. Level III nodes, which can be accessed only by dividing the pectoral tendon, are usually not removed. These are included in the radiation field, which is recommended if multiple nodes are involved. The risk of lymphedema with this procedure is quoted at 6% to 50% (135,136). Axillary reverse mapping (ARM) has been developed as a technique of identifying the lymphatic channels and nodes that drain the arm rather than the breast. In a small series of 23 patients, 86% of the ARM nodes were uninvolved, whereas 20/23 had metastatic lymph nodes in the axilla (137). Potentially, there may be an ability to avoid these structures in axillary dissection, but the success of the technique in avoiding lymphedema remains unvalidated.

Sentinel Node Biopsy

The concept of sentinel lymph node biopsy was designed to evaluate the stage of the disease in lieu of lymphadenectomy. It has revolutionized the surgical management of the axilla, and largely replaced axillary dissection in the node-negative axilla. In a recent meta-analysis involving 69 trials run between 1970 and 2003 and over 8,000 patients, the false negative rate averaged 7.3% across studies (ranging from 0% to 29%) (138).

While Dr. Donald Morton pioneered lymphatic mapping in the surgical management of melanoma (139), the simplicity and elegance of this technique was championed by Giuliano for breast cancer utilizing the blue-dye-only technique with lymphazurin dye to identify the sentinel nodes, while the radioisotopic technique followed 1-year later and is credited to Krag (88,140). Currently, a combination of these techniques has become most widely employed, although continued controversy persists on the different techniques of injection, whether they be

peritumoral, subareolar, or subdermal (141,142). Although all are likely successful in the majority of patients, the peritumoral technique may be important for posteriorly situated lesions. The subareolar technique may not drain to the internal mammary nodes (143). Methylene blue, diluted 1:4 in saline, is easily substituted for isosulfan blue, which has rare but real allergic reactions (144).

Following injection of isotope, the dissection begins with a separate axillary incision. Dissection is taken down to the clavicular fascia, which is opened. The axilla is interrogated with a hand-held receiving device, and further exploration for the “blue or hot” node is performed. The node is carefully dissected from the surrounding tissue, paying attention to close dissection, as the critical motor nerves have not been identified. Each node is subsequently removed and counted over 10 seconds; if more than 1 node comes out together, they should be separated. The node with the highest count becomes the benchmark, and all nodes with greater than 10% activity are considered sentinel nodes. If blue dye is used, any blue node or node with a blue stained lymphatic adjacent is a sentinel node. The sentinel nodes may be hot, blue, or hot and blue. Each technique used independently gives a 90% identification rate, and 95% when combined. Each agent’s benefits are inherently obvious: the visualization of the blue dye, and the audibility of the isotope. Before completion of the procedure, the axilla must be digitally evaluated for any palpable nodes, as false negativity is common with nodes replaced by tumor. Furthermore, care to try to identify low-lying nodes in the axillary tail of the breast is useful. An anatomical description by Clough divided the axilla into 4 zones, separated by the lateral thoracic vein and the second intercostal brachial nerve. In this scheme, in 242 Stage I/II breast cancer patients, the sentinel node was identified in medial to the vein 98.2% of the time, usually below the nerve (86.8%). The upper lateral zone, adjacent to the lymphatic drainage of the arm, never contained the sentinel node (145). While lymphatic mapping to the internal mammary chain has been performed, its impact on outcome remains unclear (146).

It has now been demonstrated that sentinel lymph node evaluation is feasible and accurately predicts the regional nodal status (139,140,147). The analysis of the few removed sentinel lymph nodes enabled pathologists to do multiple sections and a far more careful analysis of a few nodes, rather than a single section of the 10 to 20 nodes usually obtained from an axillary dissection. This detailed examination has sharply increased (by 20% to 30%) the proportion of “positive” nodes.

Intraoperative assessment of sentinel lymph nodes using touch imprints and routine IHC staining is used by some to enable an immediate therapeutic lymphadenectomy if the nodes were positive, thus sparing the patient from a second procedure. However, intraoperative assessment may have unacceptable rates of false-negative results, ranging from 36% to 71% (148). Not all “positive” sentinel lymph nodes require a subsequent therapeutic lymphadenectomy since studies have shown low risk of regional nodal recurrence after observation only for patients with a positive sentinel lymph node (149) and given the ACOSOG Z-11 trial. Nonetheless, patients undergoing mastectomy, neoadjuvant chemotherapy, or not receiving whole breast radiotherapy were not addressed in Z-11, and intraoperative nodal assessment continues to remain pertinent.

For this unaddressed cohort, we strive to ascertain which of the patients with a positive sentinel node need axillary node dissection. Nomograms predicting the extent of further nodal involvement have been developed and continue to assist us in the areas where Z-11 does not apply (150,151).

Current data suggest that with smaller tumor size in the era of mammographic screening, only 30% of breast cancers are node-positive at presentation. In approximately 50% to 60%, the only positive node is the sentinel node. Data from the NSABP B-04 and other trials, performed before the routine use

of systemic chemotherapy, demonstrated no survival benefit in removing the axillary lymph nodes for occult disease.

The use of axillary dissection and sentinel node biopsy comes at a cost to the patient. The incidence of lymphedema after axillary dissection and after axillary radiation is similar and higher when the two are combined. For sentinel node biopsy, the Z-10 trial found a 7% incidence of lymphedema defined as greater than 2-cm circumferential change. Overall, 50% to 70% patients have some complaint after axillary dissection, including restricted shoulder motion (17%), intercosto-brachial nerve numbness (78%), and pain (25%); though less frequent than in sentinel node biopsy patients, these problems are still possible (116). Though these problems are not life threatening, their effect on quality of life can be significant (152). The ARM technique has also been applied to sentinel node biopsy and may be useful in reducing lymphedema for this procedure as well (153).

Oncoplastic Surgery

Subsequent to the revolutionary advances taking surgeons from radical mastectomy to lumpectomy and axillary dissection, there remained a cohort of patients who required mastectomy to either resect their disease adequately, or who had significant risk of future breast carcinoma such that breast conservation was deemed inappropriate. For these patients continuing with the standard simple mastectomy, nodal evaluation lagged behind advances already achieved. Immediate reconstruction after mastectomy had been clearly documented to be safe from an oncological perspective and beneficial to a patient’s well-being for over 15 years (154). A more ideal technique of complete resection of the breast, with preservation of unaffected structures emerged and was primarily championed by Simmons et al. (155). Their landmark article compared recurrence patterns in women treated by skin-sparing mastectomy (SSM) versus non-SSM and demonstrated local recurrence rates of 3.90% and 3.25%, respectively, with an equivalent distant recurrence rate of 3.9% at 5 years.

SSM involves resection of the nipple areolar complex and nodal evaluation, when indicated, but with preservation of the entire overlying skin envelope. While initially reserved for early-stage breast cancer, Foster et al. have shown that SSM can be used in LABC stages IIB and III with comparable local recurrence (156). A recent analysis of recurrence patterns reveals that local recurrence is usually in the same quadrant as the disease and is more common with high-grade DCIS or grade 3 invasive tumors (157).

Given a retrospective analysis revealing that malignant involvement of the areola is uncommon (0.9%) (158), both the areola and nipple sparing mastectomy (NSM) have emerged as oncologically safe techniques for achieving a cosmetic mastectomy in appropriately selected patients (159,160). A recent meta-analysis of SSM and NSM versus non-SSM demonstrated equivalent local recurrence (6.2% vs. 4.0%) regardless of technique, with a follow-up of 37.5 to 101.0 months (161). In a pure NSM cohort of 658 patients, local recurrence was 2.4% at 3 year follow-up, and the complications of partial or full nipple necrosis and flap necrosis were 3.5% and 11.9%, respectively (162,163). Furthermore, the technique was extended to patients with more advanced disease, especially after neoadjuvant chemotherapy. The Milan group has used intraoperative radiotherapy (IORT) to reduce recurrence, but the risk of nipple necrosis is approximately 10% in most series (164). Intraoperative frozen section analysis of the subareolar ductal system to exclude occult disease is reported at 98.5%, but this is likely to be dependent on local expertise. The sensitivity of the preserved nipple areolar complex ranges widely in the literature.

While the reconstructed breast proved to appear more natural, the desire for improved breast conservation has remained

paramount, where we can provide not only the greatest assurance of nipple-areolar function, but to a lesser extent, minimize the sense of “violation” in the patient. Adopting techniques from breast reduction, breast surgeons have now expanded their armamentarium in achieving cosmetically desirable lumpectomy. Incorporation of breast reduction or mastopexy with lumpectomy has yielded successful results that translate to improved cosmetic outcome for patients with either macromastia or ptotic breasts. More recently, a clearer delineation of an array of techniques that utilize simple reshaping or local tissue transfer that diminishes skin retraction post lumpectomy has been developed (165). Clough has defined 3 factors, tumor size, location, and breast tissue density, that guide in the selection of appropriate oncoplastic surgical (OPS) techniques. His comprehensive quadrant-by-quadrant atlas approach to breast-conservation surgery separates techniques into two levels. Level 1 utilizes simple tissue undermining and approximation and potential nipple-areola recentralization, but without significant skin excision, whereas level II techniques permit greater tissue resection, and involve more complex procedures based on breast reduction procedures (163). Given that these techniques afford a greater volume of resection, in-breast tumor relapse remains low; the essential goal of oncoplastic surgery is greater attainment of clear margins, reduced re-excision and mastectomy, and ultimately, improved patient satisfaction and well-being.

CHEMOTHERAPY

Biologic Therapy

Biologic Therapies in HER2 Positive Breast Cancer

Approximately 20% of newly diagnosed invasive breast cancers overexpress human epidermal growth factor receptor 2 (HER2). This is associated in most, if not all, cases with the presence of additional copies of the gene that codes for the HER2 protein on chromosome 17. While the cause of this HER2 gene amplification, which is found only in the patient's breast cancer cells, is not understood, its biologic implications are clear—increased density of HER2 on the surface of the malignant cells leads to the formation of both homo- (HER2:HER2) and heterodimers with other members of the HER receptor family (HER1, HER3 and HER4), triggering activation of tyrosine kinases associated with the intracellular portions of the receptors, which in turn trigger a number of signaling pathways that enhance cancer cell growth and proliferation, resistance to apoptosis, and metastatic potential. The goal of HER2-directed therapy is to block this activation, which also has the effect of enhancing sensitivity to other antitumor treatments.

In 2007 a consensus panel of the American Society of Clinical Oncology (ASCO) and the College of American Pathologists (CAP) defined patients as having an HER2 positive (HER2+) breast cancer if either 1) at least 30% of their tumors cells exhibit uniform intense staining (3+) for HER2 by IHC stain; or 2) their tumor cells display either an average of more than 6 HER2 signals per cell or a ratio of HER2 to chromosome 17 (using a centromeric probe) (HER2/CEP17) signals by FISH of >2.0 (166). How to categorize, and thus how to treat, tumors with a subpopulation of cancer cells that display marked HER2 gene amplification but whose average FISH ratio is less than 2.0, and aneuploid tumors with numerous copies of chromosome 17 (and thus HER2) but a HER2/CEP17 ratio of less than 2.0, remains controversial.

Adjuvant Therapy for HER2+ Breast Cancer

Patients with HER2+ early-stage breast cancers are at increased risk for distant disease recurrence and death compared to patients

with HER2 negative (HER2-) cancers of identical size and stage. While adjuvant chemotherapy that incorporates both an anthracycline and a taxane, whether given concurrently or sequentially, clearly improves DFS and OS in this group of patients (167,168), they still remain at significant risk of relapse, especially if they have a larger primary tumor or axillary lymph node involvement at diagnosis. Once the addition of trastuzumab to taxane-based chemotherapy was demonstrated to be both effective and well tolerated in patients with HER2+ metastatic breast cancer (see below), studies were initiated to study its benefit in the adjuvant setting. In 2005, the initial results from 3 clinical trials—a joint analysis of two similar though not identical U.S. studies and a European study—were presented and published, each demonstrating substantial improvements in DFS and OS with the addition of trastuzumab during or after standard adjuvant chemotherapy. Results from these studies were recently updated (169,170).

In both the North Central Cancer Treatment Group (NCCTG) 9831 study and the NSABP B-31 study, patients received 4 cycles of doxorubicin 60 mg/m² and cyclophosphamide 600 mg/m² (AC) every 3 weeks followed by paclitaxel, administered at 80 mg/m² weekly for 12 weeks (NCCTG) or either 80 mg/m² weekly for 12 weeks or 175 mg/m² every 3 weeks for 4 cycles (NSABP). Patients were randomized to receive trastuzumab 2 mg/kg weekly for 52 weeks or not; all patients on the NSABP study assigned to trastuzumab started it concurrent with the paclitaxel, while a third of the patients on the NCCTG study started trastuzumab concurrent with paclitaxel and another third did not start it until after completing the paclitaxel. The comparison of concurrent vs. sequential trastuzumab is discussed below; the following focuses solely on the patients who received concurrent chemotherapy and trastuzumab. The two arms of the studies included 4,045 patients, almost all of whom had node-positive HER2+ cancers. At last report, patients assigned to trastuzumab had a 48% improvement in DFS and a 39% improvement in OS; this translated into an 8% absolute improvement in DFS and a 7.4% absolute improvement in OS at 4 years. Patients in all subgroups (defined by age, tumor size, tumor grade, hormone receptor (HR) status, and extent of nodal involvement) benefited from the addition of trastuzumab. The addition of trastuzumab was associated with an increase in serious cardiac events (symptomatic congestive heart failure or death attributed to cardiac causes) from less than 1% for the control arms to 3% to 4% in the concurrent trastuzumab arms; risk factors for cardiac events included age ≥60 years of age, pre-existing hypertension, or a low normal left ventricular ejection fraction at baseline (169).

The Herceptin Adjuvant (HERA) trial randomized 5,090 women with HER2+ cancers who had completed adjuvant chemotherapy of their physician's choice (with <25% of patients receiving both an anthracycline and a taxane) to observation or the addition of 1 or 2 years of adjuvant trastuzumab. Thus far, only results for the 1-year arm have been reported. Compared to controls, patients assigned to a year of trastuzumab had a 24% relative (6.4% absolute) improvement in DFS at 4 years. By intention-to-treat analysis, patients assigned to trastuzumab had a nonsignificant 15% relative (1.6% absolute) improvement in OS, but results are confounded by the fact that 52% of patients on the observation arm crossed over to receive adjuvant trastuzumab at a median of 22.8 months from their original randomization. While patients assigned to trastuzumab had higher rates of grade 3 to 4 adverse events, the overall incidence of serious adverse events was low, and less than 1% of patients developed symptomatic congestive heart failure (170).

Given concerns about the incidence of cardiotoxicity seen in patients with HER2+ metastatic breast cancer who received both an anthracycline and trastuzumab, and the demonstrated synergy between trastuzumab and a variety of chemotherapeutic agents *in vitro*, the Breast Cancer International Research

Group (BCIRG) 006 trial was designed to test the efficacy and toxicity of a non-anthracycline-based chemotherapy regimen plus trastuzumab against a standard anthracycline-based chemotherapy regimen with or without trastuzumab (171). 3,222 women with node-positive (72%) or node-negative HER2+ breast cancer were randomized to 4 cycles of AC followed by 4 cycles of docetaxel 100 mg/m² every 3 weeks, with or without trastuzumab 6 mg/kg every 3 weeks started concurrent with the switch to docetaxel (AC-T and AC-TH), or carboplatin AUC 6, docetaxel 75 mg/m² and trastuzumab 6 mg/kg every 3 weeks for 6 cycles (TCH). Compared to AC-T, both trastuzumab-containing regimens demonstrated significant improvements in DFS—36% relative/9% absolute for AC-TH, 25%/6% for TCH—and OS—37%/5% for AC-TH, 23%/4% for TCH—at 5 years. The differences in DFS and OS between AC-TH and TCH are not statistically significant, but the study was not powered to compare these two arms. Of note, TCH was associated with a lower rate of congestive heart failure (0.4%) than either AC-TH (2%) or AC-T (0.7%), and a lower likelihood of a sustained drop in left ventricular ejection fraction (LVEF) (9.4% vs. 18.6% for AC-TH and 11.2% for AC-T). The addition of carboplatin in the TCH arm increased the incidence of anemia and thrombocytopenia, while the lower dose of docetaxel reduced the incidence of myalgias and arthralgias, and sensory and motor neuropathy. In addition to reducing cardiac toxicity, dropping the anthracycline reduced vomiting and mucositis, and appeared to markedly reduce if not eliminate the small but real risk (0.33% in patients on AC-T or AC-TH) of developing a treatment-related leukemia.

Concurrent trastuzumab with taxane-based chemotherapy appears to be more effective than sequential treatment. In addition to the greater improvements in DFS and OS reported by the NCCTG and NSABP trials compared to HERA, a recent analysis of patients on the NCCTG study assigned to receive trastuzumab after completion of chemotherapy (172) demonstrated that while these patients still had significant improvements in DFS and OS compared to patients who did not receive trastuzumab, there was a clear trend favoring concurrent over sequential treatment (a 23% relative improvement in DFS and 22% in OS), though this did not achieve statistical significance.

As exciting as the results from the adjuvant trastuzumab trials have been, the 4 trials reviewed above all administered at least 1 year of trastuzumab (barring toxicity)—the only duration of treatment question being addressed is whether 2 years of trastuzumab is more effective than 1 (by the HERA trial). Whether this duration of treatment, and the associated costs, inconvenience, and toxicities, are necessary to achieve benefit from adjuvant trastuzumab is not clear. The Finland Herceptin (FinHer) trial randomized 232 HER2+ patients to chemotherapy (3 cycles of docetaxel 80 mg/m² or vinorelbine 25 mg/m² days 1 and 8 every 21 days) with or without 9 weeks of trastuzumab, followed by 3 cycles of FEC (173). Patients assigned to receive trastuzumab had nonsignificant trends toward improved DFS (35% relative improvement) and OS (45% relative improvement) at 5 years, and no evidence of increased cardiac toxicity. Shorter durations of adjuvant trastuzumab are currently being studied; the identification of an equally effective but briefer adjuvant trastuzumab regimen would be of great benefit in terms of optimal use of medical resources.

For high-risk HER2+ patients with no contraindication to administration of an anthracycline (no characteristics suggesting an increased risk of significant cardiotoxicity), we still favor AC followed by weekly paclitaxel with initiation of weekly trastuzumab concurrent with the paclitaxel, followed by trastuzumab 6 mg/kg every 3 weeks to complete a year of trastuzumab. In patients with any contraindication to treatment with an anthracycline, those who, after discussing treatment alternatives, opt not to receive an anthracycline, and patients with relatively low-risk (such as T1N0) cancers, we are comfortable administering the TCH regimen.

Patients who are going to receive an anthracycline-based chemotherapy regimen followed by trastuzumab should have cardiac function evaluated (with an echocardiogram or gated cardiac ejection fraction scan) prior to starting chemotherapy and prior to starting trastuzumab, after which cardiac monitoring should be individualized based on patient age, baseline ejection fraction, and risk factors for developing cardiac dysfunction. Guidelines for holding or discontinuing trastuzumab in patients with symptoms of cardiac dysfunction or a falling LVEF should be followed.

Current areas of interest include determining whether substitution of or addition of lapatinib (an HER2 tyrosine kinase inhibitor discussed in the section on treatment of HER2+ metastatic disease) to trastuzumab (concurrent or sequential) will further improve DFS and OS; this is being addressed by the Adjuvant Lapatinib and/or Trastuzumab Treatment Optimisation (ALTTO) trial (NCT00490139), which has completed accrual of 8,381 patients. There is also interest in trying to identify effective but briefer and/or less toxic chemotherapy regimens to administer with adjuvant trastuzumab. At the San Antonio Breast Cancer Symposium in 2011, early results were presented for a phase II adjuvant trial of 486 patients with lower-risk HER2+ disease (79% node-negative, 68% $T \leq 2$ cm) treated with 4 cycles of docetaxel and cyclophosphamide every 3 weeks and a year of trastuzumab. At 3 years, DFS was 95%, and OS was 99%. A phase II trial of weekly paclitaxel and trastuzumab for 12 weeks followed by single-agent trastuzumab has completed accrual of 400 patients with $T \leq 3.0$ cm, node-negative HER2+ cancers.

The role of chemotherapy and trastuzumab in patients with small (T1a or T1b), node-negative HER2+ cancers is also controversial. While some retrospective analyses have reported higher rates of overall and distant disease recurrence for patients with small HER2+ cancers compared to small HER2- cancers (174), whether all such patients warrant systemic adjuvant therapy is unclear. Our inclination is to treat patients with T1bN0 cancers, especially if they are HR-negative (HR-), unless the patient has a contraindication to receiving chemotherapy. Whether to treat any T1aN0 cancers, or T1bN0 HR positive (HR+) HER2+ cancers, is less clear. Whether patients with early-stage, HR+, HER2+ cancers, who have a better prognosis than patients with HR-, HER2+ cancers, might derive sufficient benefit from a combination of endocrine and HER2-targeted therapy to eliminate the need for chemotherapy has not been studied.

Neoadjuvant Therapy in HER2+ Disease

Given the rapid growth kinetics of HER2+ breast cancers, it is not surprising a significant percentage of patients with these cancers present with large tumors or locally advanced disease, making them good candidates for neoadjuvant therapy. While the percentage of patients with HER2+ cancers who achieve a pCR with neoadjuvant chemotherapy alone, especially those with HR-/HER2+ disease, is relatively high, blocking HER2 signaling clearly enhances the chemosensitivity of HER2+ breast cancers. Two prospective randomized studies have demonstrated significant improvements in pCR rates with the addition of trastuzumab (175,176), and a recent retrospective analysis confirmed improvement of DFS in HER2+ patients who receive trastuzumab as part of their neoadjuvant regimen.

A pooled analysis of the 2 randomized studies (177) reported that the addition of trastuzumab to the control chemotherapy regimen doubled the pCR rate, and improved both DFS and OS by 33% (though the OS increase did not reach statistical significance); treatment with trastuzumab (in both studies given concurrent with an anthracycline) was associated with a non-significant increased risk of cardiac dysfunction. In the larger of the two studies, the NOAH trial, 235 women were treated with

doxorubicin and paclitaxel followed by cyclophosphamide, methotrexate, and 5-fluorouracil plus or minus trastuzumab for 1 year. Compared to chemotherapy alone, the addition of trastuzumab increased the pCR rate from 23% to 43% and increased event-free survival at 3 years from 56% to 71%, but was associated with a 2% rate of symptomatic congestive heart failure.

These studies support the use of trastuzumab plus chemotherapy in the neoadjuvant setting for HER2+ breast cancer, but given concerns about the risk of cardiac dysfunction associated with concomitant administration of an anthracycline and trastuzumab, combining these agents should be avoided until further data on the safety of that approach become available. One standard neoadjuvant regimen for a HER2+ patient includes 4 cycles of doxorubicin and cyclophosphamide administered every 2 or 3 weeks followed by 12 weeks of weekly paclitaxel (80 mg/m²) plus trastuzumab (4 mg/kg week 1 then 2 mg/kg weekly) as neoadjuvant therapy, then single-agent trastuzumab (8 mg/kg loading dose, then 6 mg/kg every 3 weeks) after surgery to complete a full year of the biologic treatment. This is similar to the most effective trastuzumab-containing regimen from the NCCTG adjuvant trial (169).

Other appropriate neoadjuvant regimens for patients with HER2+ cancers include those used as adjuvant treatment in early-stage HER2+ breast cancer, such as AC followed by paclitaxel or docetaxel every 3 weeks, with initiation of the trastuzumab concurrent with the taxane, or a non-anthracycline-containing regimen such as docetaxel, carboplatin and trastuzumab (TCH) every 3 weeks for 6 cycles or even, in lower-risk HER2+ patients, docetaxel, cyclophosphamide, and trastuzumab every 3 weeks for 4 to 6 cycles (based on I1). A phase II study of neoadjuvant dose-dense TCH (administered every 2 weeks for 6 cycles) in 48 HER2+ patients reported a pathologic complete response rate of 36%.

More recently, there has been interest in administration of dual HER2-targeted treatments together with neoadjuvant chemotherapy to overcome potential trastuzumab resistance. The NeoAdjuvant Lapatinib and/or Trastuzumab Treatment Optimization (Neo-ALTTO) trial randomized 453 women with stage II-III HER2+ breast cancers to lapatinib 1,500 mg daily, trastuzumab, or the combination of trastuzumab and lapatinib 1,000 mg daily (178). Patients received 6 weeks of HER2-targeted therapy alone, followed by 12 weeks of weekly paclitaxel (80 mg/m²) along with their assigned HER2-targeted treatment, then underwent surgery. Patients were assessed for response after the initial 6 weeks of targeted therapy as well as prior to surgery using physical exam, mammogram, and US or breast MRI. Patients assigned to the trastuzumab/lapatinib combination had a significant higher clinical response rate at the end of biologic therapy alone (67 vs. 30 and 52% with single-agent trastuzumab or lapatinib, respectively) and at the time of surgery (80 vs. 71 and 74%, respectively), a significantly higher pCR rate (51 vs. 30 and 25%, respectively), higher pCR rates in both hormone receptor positive and hormone receptor negative patients, but similar rates of BCS (41 vs. 39 and 43%, respectively). There were more serious (grade 3/4) adverse events in the groups treated with lapatinib than in the group treated with trastuzumab alone. These consisted of diarrhea, elevated transaminases, neutropenia (only during administration of paclitaxel), and rash. However, no significant cardiac adverse events were reported in any of the 3 arms.

Pertuzumab is a humanized monoclonal antibody that blocks the dimerization domain of HER2, preventing the formation of HER2 heterodimers with HER3 as well as other members of the HER receptor family. The formation of HER2:HER3 heterodimers is a proposed mechanism by which HER2+ breast cancer cells may bypass inhibition by trastuzumab. Since pertuzumab binds to a different region of HER2 than trastuzumab, dual HER2-targeting with the trastuzumab and pertuzumab

combination is being evaluated in the neoadjuvant as well as the metastatic setting (see below). The NeoSPHERE trial was an open-label randomized phase II trial that enrolled 417 women with operable, locally advanced, or inflammatory HER2+ breast cancer and randomly assigned them to 12 weeks of treatment using 1 of 4 regimens: docetaxel (100 mg/m² every 3 weeks for 4 cycles) plus trastuzumab (group A), docetaxel plus trastuzumab and pertuzumab (group B), pertuzumab plus trastuzumab alone (group C), or docetaxel plus pertuzumab (group D) (179). After surgery, patients on the docetaxel arms received 3 cycles of FEC then completed a year of trastuzumab, while patients in group C received both docetaxel and FEC followed by trastuzumab. pCR rates were 29%, 46%, 17%, and 24% in groups A, B, C, and D, respectively. Compared to women with HR+ disease, the pCR rates were generally higher in women with HR-tumors. Serious (grade 3/4) adverse events in patients treated with docetaxel (groups A, B, D) included neutropenia, febrile neutropenia, and diarrhea. The addition of pertuzumab to the docetaxel plus trastuzumab combination did not appear to increase toxicity, including any increase in the low incidence of cardiac adverse events. Few adverse events occurred in women receiving combined HER2 treatment without docetaxel (group C). These results are fascinating not only because of the higher pCR rate seen on the chemotherapy plus trastuzumab and pertuzumab arm, but also because of the frequency of pCRs associated with dual HER2-targeted therapy alone, raising the intriguing possibility that there may be a subset of HER2+ patients who can be effectively treated without the toxic effects of chemotherapy.

Treatment of HER2+ Metastatic Breast Cancer

The central role of HER2 activation in the survival and growth of HER2+ breast cancers is illustrated by the single-agent antitumor activity of trastuzumab, lapatinib, and other HER2-targeted therapies. However, they have an even greater impact when given together with cytotoxic chemotherapy, as in the pivotal phase III study that compared standard first-line chemotherapy with either doxorubicin and cyclophosphamide (AC), or single-agent paclitaxel (in patients not eligible to receive an anthracycline), alone or with the addition of trastuzumab (60). Addition of the targeted therapy not only improved response rates (RR) and time to progression (TTP), but prolonged OS (25 vs. 20 months) despite a high percentage of patients on the control arm crossing over to receive trastuzumab after disease progression. That study was also the first to demonstrate the additive or synergistic cardiotoxicity of anthracyclines and trastuzumab, as a result of which the combination of paclitaxel and trastuzumab became the initial standard regimen. Since then, trastuzumab has been shown to improve RR, TTP, and OS with a variety of different chemotherapeutic agents. Only one relatively small study has compared concurrent chemotherapy (docetaxel) plus trastuzumab to sequential single-agent trastuzumab followed by docetaxel (180), and while progression-free survival (PFS) was similar across the two arms, patients on concurrent therapy had higher RR and a trend toward improved OS (30.5 vs. 19.7 months).

The optimal first-line chemotherapy plus trastuzumab combination is not known, as few have been tested head-to-head. While taxane (usually weekly paclitaxel at 80 mg/m² or q3week docetaxel at 75 to 100 mg/m²)-based regimens remain common, some doctors and patients will opt for regimens not usually associated with hair loss, such as vinorelbine-, gemcitabine-, capecitabine- or liposomal doxorubicin-trastuzumab. Combinations of chemotherapeutic agents given with trastuzumab may (paclitaxel and carboplatin vs. single-agent paclitaxel) or may not (docetaxel and carboplatin vs. single-agent docetaxel) produce higher RR and improved TTP, but have not been shown to improve OS (181,182).

When a patient has achieved maximal benefit from a chemotherapy-trastuzumab combination or starts to develop cumulative toxicities, she is often switched to single-agent trastuzumab “maintenance” therapy, a logical strategy given the level of activity of single-agent trastuzumab but has not been tested in a randomized trial. What is clear is that HER2+ patients progressing on treatment retain sensitivity to HER2-targeted therapies. Patients progressing on trastuzumab who were randomized to capecitabine with continuation of trastuzumab had superior TTP (8.2 vs. 5.6 months) and OS (25.5 vs. 20.4 months) to patients assigned to single-agent capecitabine (183). Even before these results became available, it had been routine practice in patients with HER2+ metastatic breast cancer who were progressing on one chemotherapy-trastuzumab combination to change the cytotoxic agent but continue trastuzumab.

Lapatinib is a small molecule oral tyrosine kinase inhibitor that blocks activation of pathways triggered by either the epidermal growth factor receptor (EGFR, also called HER1) and HER2. Its most common toxicities, including diarrhea and an acneiform rash, appear to be caused by blockade of EGFR-stimulated pathways, as they are similar to those seen with EGFR-targeted monoclonal antibodies. It has modest single-agent activity in patients with HER2+ metastatic breast cancer who have progressed on trastuzumab, but, in patients previously treated with an anthracycline, taxane, and trastuzumab, the combination of capecitabine and lapatinib bested single-agent capecitabine in terms of TTP (6.2 vs. 4.3 months) and OS (75.0 vs. 56.4 weeks) (184).

Interest in lapatinib is stimulated in part by its ability to counteract some mechanisms of resistance to trastuzumab and to penetrate into areas, like the central nervous system, that trastuzumab cannot reach.

The potential merit of combined HER2 pathway blockade by agents with differing mechanisms of action is illustrated by the following studies: patients with HER2+ metastatic breast cancer who had progressed on one or more trastuzumab-containing regimens were assigned to treatment with single-agent lapatinib vs. lapatinib and trastuzumab (185); patients on the combination arm had a superior clinical benefit rate (24.7 vs. 12%), improved TTP (12 vs. 8 weeks) and a nonsignificant improvement in OS (52 vs. 39 weeks), which was likely confounded by the 49% of patients randomized to single-agent lapatinib who crossed over to the combination arm after early disease progression. In the first-line metastatic setting, 808 HER2+ patients received docetaxel 75 mg/m² and trastuzumab, and were randomized to the HER-dimerization blocker pertuzumab or placebo (186). Patients assigned to the dual-targeted agents had improved RR (80 vs. 69%; PFS, 19 vs. 12 months) and a trend toward improved OS. The addition of pertuzumab was associated with higher rates of diarrhea, mucositis, rash, and febrile neutropenia (14 vs. 8%), but no increase in cardiac toxicity.

In approximately half of the patients with HER2+ breast cancer, the tumor cells also express hormone receptors. Data from the combined analysis of the NCCTG N9831 and NSABP B-31 adjuvant trials suggest that patients with early-stage HER2+ cancers whose tumors co-express hormone receptors (HR+) have an improved prognosis whether they get trastuzumab with their adjuvant chemotherapy (4 years DFS of 89.4 vs. 81.6% for HR negative [HR-] or not (77.2 vs. 69.4%), with no decrement in the benefit from the targeted agent (169). While patients with HR+/HER2+ cancers are less likely to achieve a pathologic complete response with neoadjuvant chemotherapy plus trastuzumab, their overall prognosis is better than for patients with HR-/HER2+ cancers. On average, patients with advanced stage HR+/HER2+ cancers live longer than HR-/HER2+ patients with HER2+/HR- cancers. This presumably reflects differences in tumor biology, such as proliferative rate. While results from individual studies vary, a meta-analysis of 12 studies involving 2,379 patients with HR+ MBC treated with various endocrine

therapies demonstrated that PFS for HR+/HER2+ patients was 42% shorter compared to HR-/HER2- patients (187). The addition of an HER2-targeted agent at least partially reverses this disadvantage. The TAnDEM trial randomized 207 postmenopausal patients with HR+/HER2+ metastatic breast cancer to anastrozole with or without trastuzumab (188). Patients treated with the combination had improvement in PFS (4.8 vs. 2.4 months), as well as improved response (20.3% vs. 6.8%), and clinical benefit (42.7% vs. 27.9%) rates; the absence of a significant improvement in OS (28.5 vs. 23.5 months) may have been caused by the fact that 70% of patients assigned to anastrozole alone received trastuzumab at some point in their subsequent treatment. A double-blind study of letrozole with either lapatinib 1,500 mg daily or placebo in HR+ patients with metastatic breast cancer included 219 postmenopausal patients who were considered HER2+ (189). In these patients, the addition of lapatinib improved PFS from 3.2 to 8.0 months, RR from 15% to 28%, and clinical benefit rate from 29% to 48%. HR+/HER2- patients did not benefit from the addition of lapatinib. Side effects were those that would be expected with this dose of lapatinib. These results suggest that in older patients with less extensive or minimally symptomatic metastatic HR+/HER2+ cancer, a trial of endocrine therapy plus a HER2-targeted therapy (with close monitoring for disease progression) could be considered.

Other Biologic Therapies

Bevacizumab and Other Angiogenesis Inhibitors

Bevacizumab is a partially humanized monoclonal antibody, which was designed to bind vascular endothelial growth factor (VEGF) and inhibit tumor-stimulated neoangiogenesis. It is approved as a single agent or in combination with chemotherapy to treat a variety of advanced solid tumors. In patients with advanced breast cancer, it has modest activity as a single agent. However, when given in combination with weekly paclitaxel (90 mg/m² days 1, 8, and 15 mg/m² every 28 days) on the ECOG 2100 study, the addition of bevacizumab improved RR (37% vs. 21%) and PFS (11.8 vs. 5.9 months) compared to single agent paclitaxel (190), for which the drug was granted preliminary FDA approval even though it did not improve OS (26.7 vs. 25.2 months). In a number of several subsequent randomized, double-blinded studies in the first- or second-line metastatic setting (AVADO, RIBBON-1, RIBBON-2), the addition of bevacizumab to a variety of chemotherapeutic agents improved RR and PFS, but again failed to prolong OS. Treatment with bevacizumab is associated with a 10% to 20% incidence of hypertension requiring treatment, proteinuria, an increase in thromboembolic events, and more frequent hematologic and nonhematologic toxicities related to the concurrent chemotherapy regimen. In other patient populations treated with bevacizumab, an increase in stroke, myocardial infarction, impaired cardiac function, wound dehiscence, and bowel perforation had been reported but were not seen in the advanced breast cancer population. Weighing the benefits of delayed disease progression in the absence of a survival advantage against the risks associated with the drug, in November 2011 the FDA revoked its provisional approval as part of first-line therapy in metastatic breast cancer. However, since the drug is approved for several other indications, it remains an available option for patients with advanced breast cancer.

Results of two studies in the neoadjuvant setting suggest that bevacizumab can improve the pCR rate in selected patients, though which group of patients may benefit is less clear. In the GeparQuinto study (191), the addition of bevacizumab to neoadjuvant chemotherapy consisting of 4 cycles of epirubicin and cyclophosphamide followed by four cycles of docetaxel in 1,948 patients with HER2- breast cancer increased the pCR rate from 27.9% to 39.3% in patients with triple-negative cancers (a 67% improvement), but had no effect on the pCR rate in patients

with HR+ cancers (7.8 and 7.7%). In contrast, in the NSABP B-40 study (192), the addition of bevacizumab to 4 cycles of docetaxel-based therapy followed by 4 cycles of AC in 1,206 HER2- cancers improved the pCR in HR+ patients from 15.1% to 23.2% (a 54% increment) while having a minimal impact in the triple-negative cohort (47.1% to 51.5%). What impact, if any, these differences will have on long-term outcomes such as DFS and OS is not known.

A number of completed (but not reported) and ongoing large, randomized studies of bevacizumab in the adjuvant and neoadjuvant settings should shed further light on whether this agent will have a role in the management of early-stage breast cancer in the future.

A number of small molecule tyrosine kinase inhibitors that target the VEGF receptor, including sunitinib, sorafenib, axitinib, and pazopanib, have been studied in patients with advanced breast cancer; thus far, none of these agents have demonstrated substantial benefits in this population. Aflibercept, also referred to as VEGF-trap, functions as a soluble decoy receptor, binding circulating VEGFs and preventing them from binding to (and activating) their cellular receptors.

Other Biologic Agents of Interest

The epidermal growth factor receptor (EGFR) is overexpressed in a subset of aggressive, poorly responsive breast cancers, including some triple-negative cancers. Agents that block this receptor, including monoclonal antibodies that block its extracellular ligand-binding domain like cetuximab, and small molecules that block its intracellular tyrosine kinase domain like gefitinib and erlotinib, have been tested in advanced breast cancer but exhibit little antitumor activity. Inhibitors of poly (ADP-ribose) Polymerase-1 (PARP-1) interfere with base excision repair, an important mechanism of DNA repair in cells with defects in homologous recombination, such as those with mutations in or inactivation of the breast cancer associated *BRCA1* and *BRCA2* genes, and some triple-negative cancers. As single agents, some PARP inhibitors have demonstrated activity against breast cancers in patients with *BRCA* mutations, but their usefulness in patients with sporadic triple-negative cancers, either alone or in combination with DNA-damaging chemotherapy, has yet to be demonstrated.

As our understanding improves of the complex pathways that influence the behavior of normal cells and of how aberrations of those pathways give rise to the hallmarks of malignancy, we may be able to target those abnormalities to the benefit of our patients. For example, everolimus is an oral mTOR (mammalian target of rapamycin) inhibitor that blocks the phosphoinositide 3-kinase (PI3k)-Akt signal transduction pathway. It is FDA approved as a single agent to treat advanced renal cell carcinoma and pancreatic neuroendocrine tumors in addition to its role as an immunosuppressive agent following solid organ transplants. The phase III Breast cancer trials of Oral everolimus-2 (BOLERO-2) study randomized 724 postmenopausal patients with HR+ breast cancers who had progressed on a nonsteroidal aromatase inhibitor (166) (anastrozole or letrozole) to the steroidal AI exemestane with everolimus 10 mg/d or placebo. Patients assigned to take everolimus had higher RR and clinical benefit rates, and a significant improvement in median PFS (11.0 vs. 4.1 months). Further study of this and other inhibitors of the PI3k-Akt pathway would appear to be warranted.

Bisphosphonates as Adjuvant Therapy

Bisphosphonates are potent inhibitors of osteoclast activation and have been shown to reduce bone mineral loss in women with natural and treatment-induced menopause, and to reduce the frequency of fractures and bone pain in breast cancer patients with bone metastases. Pre-clinical studies have suggested that bisphosphonates may also possess antitumor activity, including

antiangiogenic, antiproliferative, and proapoptotic effects. Bisphosphonate-induced osteoclast inhibition might make the bone microenvironment less supportive of tumor cell proliferation, and epidemiologic data suggest that bisphosphonates used in the management of osteopenia and osteoporosis may decrease the risk of developing breast cancer.

Data on the value of bisphosphonates as adjuvant therapy are conflicting. In the NSABP B-24 study of 3,323 women with early-stage breast cancer, all of whom received adjuvant chemotherapy ± endocrine therapy, 3 years of clodronate (1,600 mg/d) was compared to placebo and demonstrated trends favoring the oral bisphosphonate for improved recurrence-free survival and OS, but no statistically significant differences. Combined analysis of two studies (Z-FAST and Zo-FAST) that compared immediate versus delayed (treatment deferred until a drop in bone density) administration of the potent IV bisphosphonate zoledronic acid 4 mg every 6 months for 5 years in patients taking adjuvant letrozole suggested a cancer recurrence benefit for the immediate treatment group (193). The strongest evidence favoring adjuvant bisphosphonates comes from the Austrian Breast and Colorectal Cancer Study Group (ABCSG)-12 study. A total of 1,803 premenopausal women with HR+ breast cancers were treated with ovarian suppression and either tamoxifen or anastrozole (no patients received adjuvant chemotherapy), and were randomized to receive zoledronic acid 4 mg every 6 months for 3 years or not. Updated results from this study demonstrate that those patients who received zoledronic acid had a 28% improvement in DFS and a 40% improvement in OS, with benefits seen only in older (>40 years of age) patients. In contrast, a larger study, the Adjuvant Treatment With ZOL in Stage II/III Breast Cancer (AZURE, BIG 01/04), randomized 3,360 patients, almost all of whom received adjuvant chemotherapy, to a longer, more intensive zoledronic acid regimen or not (194). At 5 years, there were no overall differences in DFS or OS, though in the subset of women who were at least 5 years postmenopausal at study entry, zoledronic acid did improve DFS and OS.

Chemotherapy for Breast Cancer

Cytotoxic chemotherapy is commonly given to patients with early- and advanced-stage breast cancer whose disease is either hormone insensitive (ER and PR negative), has developed resistance to endocrine therapy, has high-risk features, including low expression of ER and PR, HER2 gene amplification, high grade or a high proliferative rate, evidence of rapid tumor growth, or, in patients with metastatic disease, has evidence of extensive involvement of one or more vital organs. Concepts that often arise in a discussion of chemotherapy include:

Dose Intensity

When studied in the laboratory, for many chemotherapeutic agents, higher drug concentrations result in increased killing of cancer cells, displaying what is referred to as a dose-response curve. When treating patients with breast cancer, it is less clear that more is always better, and with increased dose, the toxic effects of the drug almost always increase. For example, in the adjuvant setting, the Cancer and Leukemia Group B (CALGB) 8541 study demonstrated that administering what are now standard doses of cyclophosphamide, doxorubicin, and 5-fluorouracil (CAF) improved DFS and OS, especially in patients with more aggressive cancers, compared to lower doses of the same drugs (195,196), while a subsequent study, CALGB 9344, failed to show further benefit from raising the doxorubicin dose from 60 mg/m² to its highest tolerated level (90 mg/m²) (197). The ultimate test of dose intensity involves administration of such high doses of chemotherapy that the patient requires autologous hematopoietic stem cell support for recovery of blood counts, sometimes

referred to as a bone marrow transplant. While initial studies suggested that such an approach might be better than standard dose chemotherapy, subsequent larger, randomized trials clearly demonstrated that this treatment, whether administered as adjuvant therapy for high-risk patients or for metastatic disease, is no more effective than standard dose therapy and associated with a much higher rate of serious and life-threatening side effects. (198)

Dose Density

In contrast to administering higher individual doses of one or more chemotherapeutic agents, this involves administering similar or lower doses of one or more agents more frequently. This often allows administration of a higher overall dose of a drug with less toxicity, and also may increase the drug's cytotoxic effects by increasing the likelihood of catching a higher proportion of cancer cells in the most vulnerable phases of their cell cycle. Examples of this include CALGB 9840, which demonstrated the superiority of weekly paclitaxel over every 3 week (q3week) paclitaxel in patients with metastatic breast cancer (199); CALGB 9741, which demonstrated improvements in DFS and OS in patients with node-positive breast cancer who received the same total number of cycles of doxorubicin and cyclophosphamide (AC) followed by paclitaxel q2weeks (with granulocyte-colony stimulating factor [G-CSF] support) as opposed to the standard schedule (q3weeks) (200); and ECOG 1199, which demonstrated superior DFS and OS in node-positive patients who received weekly paclitaxel compared to q3week paclitaxel after 4 cycles of AC (201). This strategy also has its limitations, as illustrated by initial results from the Southwest Oncology Group (SWOG) 0221 adjuvant study in which a regimen of weekly doxorubicin and daily oral cyclophosphamide was not superior to q2week AC. Another example of dose density is what is referred to as metronomic chemotherapy in which patients with metastatic disease receive low daily or twice weekly doses of (usually oral) chemotherapy (202); this approach has demonstrated some efficacy with relatively little toxicity in patients who had progressed after a number of standard dose chemotherapy regimens, though it has not yet been directly compared to other forms of salvage chemotherapy.

Non-Cross-Resistant Drug Combinations

To increase the effectiveness of treatment, in choosing which chemotherapeutic agents to administer, either concurrently or sequentially, it is best to select agents with different mechanisms of action, different mechanisms of drug resistance, and, when possible, nonoverlapping toxicities. Switching to a non-cross-resistant drug or regimen may improve response, even when the patient is responding to the initial regimen. An example of this is the Aberdeen neoadjuvant trial, in which patients whose tumors were responding after 4 cycles of a doxorubicin-based regimen were randomized to continue the same regimen for 4 additional cycles or were switched to 4 cycles of docetaxel (203). At the completion of treatment, patients switched to docetaxel had higher rates of clinical and pathologic complete response, and subsequently improved DFS and OS. In the adjuvant setting, patients receiving 5-fluorouracil, epirubicin, and cyclophosphamide (FEC) who were randomized to switch to either weekly paclitaxel or q3week docetaxel had improved DFS compared to patients who continued on FEC (204,205).

Combination versus Sequential Single-Agent Chemotherapy

An ongoing controversy is whether breast cancer patients, especially those with metastatic disease, do better with combinations of chemotherapeutic agents or administration of individual

agents, switching to another agent upon disease progression. This is discussed in greater detail later. In general, combination chemotherapy results in higher response rates and a modest increase in time to disease progression (TTP), but has little impact on OS. Thus, combinations may be appropriate in situations where rapid response is vital, such as in patients with diffuse symptomatic disease or extensive involvement of vital organs such as the liver or lungs (referred to as visceral crisis), whereas single agents may be more appropriate in patients with less extensive or symptomatic disease, and in older or frail patients less likely to tolerate a combination. The question of sequential single agents vs. combinations has been studied less in the adjuvant setting, but in the CALGB 9741 study mentioned above, patients were also randomized to q2week sequential single-agent doxorubicin, paclitaxel, and cyclophosphamide, and these patients did as well as patients randomized to q2week AC followed by paclitaxel (201).

Adjuvant Chemotherapy

When discussing adjuvant chemotherapy, the first question to address is who should receive it. Almost all patients with either triple-negative (TNBC, defined as ER and PR expressed on less than 1% of tumor cells by IHC stain and HER2- by IHC 0-1+ or FISH <2.0 if IHC 2+) or HER2+ cancers, unless contraindicated by age and major comorbid medical problems, should receive adjuvant chemotherapy, together with trastuzumab in HER2+ patients (see discussion of treatment of HER2+ cancers in the section on biologic therapies). Whether adjuvant treatment is necessary in patients with TNBC or HER2+ tumors <1.0 cm and negative lymph nodes is unclear; while retrospective analyses clearly demonstrate that such patients have a higher risk of recurrence than patients with small HR+/HER2- cancers, they still have a relatively good prognosis (174,206). Many (but far from all) oncologists recommend adjuvant treatment to patients with TNBC and HER2+ tumors 0.6 to 1.0 cm (T1b) and discuss adjuvant treatment with patients whose tumors are <0.5 cm (T1a) if they are both HER2+ and HR-.

If the oncologist is uncertain if he or she is accurately estimating a patient's risk of recurrence and potential benefit from adjuvant chemotherapy, an available resource to assist in this process is the free online service *Adjuvant!* (www.adjuvantonline.com). The *Adjuvant!* program compares a patient's baseline tumor characteristics with those from two large databases to approximate her risk of distant disease recurrence, then applies results from major clinical trials and actuarial projections based on the patient's age and overall health status to estimate the reduction in disease recurrence that would be expected from administration of adjuvant endocrine therapy (in ER+ patients) and/or chemotherapy measured against the patient's risk of dying of other causes over the next 10 years. While far from perfect—among other limitations, its estimates separate prognostic variables, such as tumor size and number of lymph nodes involved, which are known to be continuous, into discrete categories; it does not currently take lymphovascular invasion (LVI), the size of nodal metastases, or HER2 status into account; and it assumes that all patients receive the same relative risk reduction from a given chemotherapy regimen independent of tumor characteristics—*Adjuvant!* can be used to corroborate the oncologist's assessment and to communicate the concepts of risk and risk reduction to patients and their family members.

In patients with lower risk ER+/HER2- cancers—smaller primary tumors with no or minimal axillary lymph node involvement—the value of adding adjuvant chemotherapy after taking into account the substantial risk reduction expected from adjuvant endocrine therapy is often modest. The NSABP B-20 trial demonstrated improvements in DFS and OS with adjuvant CMF in patients with ER+, node-negative cancers, but with a

high number of patients needed to treat to benefit one (207). Given this, efforts have been made to develop a test that could differentiate patients likely to do well with adjuvant endocrine therapy alone from those who would be expected to receive greater relative benefit from the addition of chemotherapy. Two such tests, both of which use gene expression arrays—using the level of expression of messenger RNA (mRNA) for a variety of genes to characterize the cancer and predict its biologic behavior—are licensed in the U.S.

Oncotype DX® is a pCR-based array that measures gene expression by mRNA for a total of 16 cancer-related genes, some of which reflect its level of estrogen stimulation (and thus likely sensitivity to endocrine therapies) and some of which correlate with cell proliferation and metastasis (associated with relative insensitivity to endocrine therapies and potential greater benefit from chemotherapy), relative to 5 “housekeeping” genes. Paik et al. have demonstrated that the recurrence score (RS) derived from the levels of expression of these genes is both prognostic for risk of recurrence in untreated patients and predictive of degree of risk reduction achieved with endocrine therapy (specifically tamoxifen) and CMF chemotherapy (R, S). The assay is performed on paraffin-embedded tissue, thus it can be sent any time after the surgical procedure. The assay is most useful when a patient’s RS is in the low end of the range (≤ 10), indicating a low-grade, very hormone-responsive cancer for which adjuvant endocrine therapy should prove very effective and chemotherapy would offer little benefit, or in the upper end of the range (>25), indicating a more aggressive cancer for which endocrine therapy alone has relatively little effect and in which adjuvant chemotherapy is more likely to be beneficial. A large clinical trial—TAILORx (ECOG-PACCT-1, NCT00310180), in which patients with a low RS are assigned to endocrine therapy only, high RS patients are assigned to receive chemotherapy followed by endocrine therapy, and patients in the middle (of the range 11–25) are randomized to receive chemotherapy or not—designed to confirm the prognostic and predictive value of the test in ER+, node-negative patients, has completed enrollment. More limited data support its use in patients with a limited number (1–3) of involved axillary nodes (208); this is being tested in an ongoing trial, RxPONDER (SWOG 1007, NCT01272037), on which patients with low-intermediate RS (0–25) are randomized to chemotherapy followed by endocrine therapy vs. endocrine therapy only. Studies have demonstrated that RS is also predictive of benefit with an aromatase inhibitor (anastrozole) (209). A study that compared predicted results obtained for the same tumors from the *Adjuvant!* database with analysis by Oncotype Dx concluded that the gene expression assay provided additional prognostic and predictive information (210). An attempt to improve the biologic Oncotype assay by incorporating the cancer’s clinical and pathologic features demonstrated that while the revised RS did improve its prognostic accuracy and reduce the number of patients with intermediate scores, this did not improve its ability to predict benefit from adjuvant chemotherapy (211).

MammaPrint® is a microarray-based gene expression assay that measures mRNA levels for 70 genes that reflect tumor proliferation, invasion, and angiogenesis. The score derived from this assay has been shown to be prognostic of risk of recurrence in patients with ER+, node-negative cancers (212,213), but it has not yet demonstrated the ability to predict benefit from the addition of adjuvant chemotherapy to endocrine therapy. Also, because of the methodology of the assay, it requires fresh tissue, which may limit its usefulness. This assay is also being studied in a prospective clinical trial called MINDACT (Microarray in Node-Negative Disease May Avoid Chemotherapy, NCT00433589), which is designed to determine if ER+ patients with 0 to 3 involved lymph nodes considered higher risk by clinical features but low risk by MammaPrint can be spared chemotherapy.

In addition to these commercially available assays, evaluation of a large number of breast cancers by broader gene expression analyses demonstrates that their patterns of expression can be divided into a limited number of what are called intrinsic subtypes, though there remains a good deal of heterogeneity of gene expression within these designations (214). Luminal A and luminal B tumors tend to be ER+ and are expected to benefit from endocrine therapies, though the somewhat more aggressive luminal B tumors also display sensitivity to chemotherapy. The basal-like (the majority of TNBC) and HER2 (largely ER-/HER2+ tumors) subtypes are more aggressive and require cytotoxic therapy. Analysis by gene expression array demonstrates that a significant fraction of patients may be mischaracterized by IHC results alone. However, assays based on this more in-depth analysis of gene expression are not yet approved for routine clinical use.

Recent Meta-Analyses of Adjuvant Chemotherapy

The EBCTCG recently updated their ongoing meta-analyses of the role of adjuvant chemotherapy in early-stage breast cancer, and for the first time added an analysis of the benefits of the addition of a taxane (paclitaxel or docetaxel), concurrently or sequentially, to anthracycline-based adjuvant chemotherapy (215). Overall, in older trials, which included a no-chemotherapy arm, administration of anthracycline-based adjuvant chemotherapy reduced breast cancer recurrences by 27%, resulting in an absolute improvement in the 10-year recurrence rate of 8.0% (39.4% vs. 47.4%), a 6.5% reduction in breast cancer-related mortality and a 5.0% improvement in overall mortality. Chemotherapy regimens which included 6 cycles of cyclophosphamide with standard doses of either doxorubicin or epirubicin and 5-fluorouracil (CAF or CEF) resulted in larger relative improvements in OS (36%) than regimens in which patients receive just 4 cycles of standard-dose doxorubicin or epirubicin with cyclophosphamide (AC or EC) (22%). Compared to no-chemotherapy controls, administration of CMF was associated with a 30% relative reduction in breast cancer recurrence (29.6% vs. 39.8%), which resulted in a 6.2% improvement in breast cancer mortality and a 4.7% improvement in overall mortality. All of these results were highly statistically significant due to the large numbers of women involved (8,575 women in the anthracycline-based trials, 5,253 in the CMF trials). The difference in the outcomes for the control groups likely reflects different patient populations, with only 18% of patients treated on the anthracycline-based trials having node-negative cancers compared to 66% on the CMF trials. Benefits from chemotherapy were essentially equivalent across multiple patient subgroups, including age, node status, HR status, and tumor grade, and administration of adjuvant endocrine therapy (tamoxifen) did not reduce the benefit of receiving adjuvant chemotherapy.

A number of studies have compared anthracycline-based regimens with standard or near-standard CMF. Studies on which patients (9,527 women, of whom 53% were node-positive) received higher cumulative doses of anthracycline (such as 6 cycles of CAF or CEF) demonstrated superiority of anthracycline-based therapy, with a relative 11% reduction in breast cancer recurrences, corresponding to a 2.6% absolute benefit, a 20% reduction in breast cancer mortality (4.1% absolute), and a 16% reduction in overall mortality (3.9% absolute). In contrast, studies which compared briefer anthracycline-based regimens, such as 4 cycles of AC or EC, to CMF (5,122 women, of whom 61% were node-positive), failed to show improvement in outcomes.

In regards the benefits of adding a taxane to anthracycline-based adjuvant chemotherapy, the recent meta-analysis identified an overall relative reduction in breast cancer recurrence of 14%, breast cancer mortality of 13%, and overall mortality of 11%. Studies in which the taxane was added to an anthracycline regimen of standard duration demonstrated the greatest

benefit for the new class of agents, including a 16% reduction in recurrences (4.6% absolute), 14% improvement in breast cancer mortality (2.8% absolute), and 14% improvement in overall mortality (3.2% absolute), while studies in which patients on the nontaxane arm continued on their anthracycline-based regimen to match the duration of treatment of patients assigned to receive the taxane failed to show significant improvements in outcomes. The aggregate results were consistent across age groups, nodal status, and HR status, the latter despite analyses of 2 large studies that suggested a lack of benefit to the addition of a taxane in patients with ER+/HER2-cancers (167,168). Assessing these results is confounded by shorter follow-up than for the chemotherapy/no chemotherapy and anthracycline/CMF comparisons discussed above, and a fair amount of heterogeneity in the control and experimental treatment regimens, including whether the taxane was administered sequentially or concurrently with the anthracycline. In the majority of studies included in this meta-analysis, the taxane (whether paclitaxel or docetaxel) was administered q3weeks, thus potentially underestimating the benefits of dose-dense q2week or weekly paclitaxel. While the results might suggest that patients would do as well with 6 cycles of CAF or CEF q3weeks as with briefer exposure to an anthracycline followed by a taxane, studies that most directly compared these approaches, including the PACS 01 and the German AM02 trials of 6 cycles of FEC vs. 3 cycles of FEC or EC followed by 3 cycles of docetaxel, demonstrated improvement in DFS and OS with the sequential regimen, as well as fewer cardiac and hematologic adverse events (204,205).

A meta-analysis of 10 trials that compared standard versus dose-dense adjuvant chemotherapy reported that dose-dense treatment was associated with relative improvements in DFS (17% to 19%) and OS (15% to 16%), whether the dose-dense regimen used similar or modified chemotherapy doses compared to the control regimen. However, this difference was seen only in patients with ER-negative cancers (in whom the DFS benefit was 29%), not in patients with ER+ cancers (8% benefit, which did not reach statistical significance).

While useful to detect treatment effects that might not be apparent or statistically significant in an individual study, a meta-analysis is limited by its tendency to lump sometimes substantially different patient groups and treatments together; for example, are the node-positive patients of 20 years ago the same as the node-positive patients of 2012, with widespread use of sentinel node sampling, and is lower-dose weekly paclitaxel the same treatment as higher-dose q3week paclitaxel? The meta-analyses are likely more useful to help to estimate the magnitude of a treatment effect than for current treatment recommendations.

Recent Trials of Adjuvant Chemotherapy

Updated results from the U.S. Oncology Trial 9735, which compared 4 cycles of AC to 4 cycles of docetaxel and cyclophosphamide (TC) q3weeks in 1,016 patients, of whom half were node-positive and 71% ER+, at a median of 7 years follow-up, continue to demonstrate superiority of the TC regimen, with a 26% improvement in DFS, which translated into a 6% absolute increase, and a 31% rise in OS (5% absolute) (216). The DFS benefit was apparently independent of age, nodal status, and HR status (though not statistically significant in the subgroups). Short-term toxicities were comparable across the 2 arms of the study, but 4 patients on the AC arm have died of possible late complications of treatment, one with congestive heart failure, and 3 with leukemia or myelodysplasia. Though of relatively modest size, this study has had a major impact on the treatment of patients with low- to intermediate-risk disease in the U.S., presumably due to the appeal of avoiding exposure to an anthracycline without (apparently) sacrificing efficacy.

CALGB 49907 compared standard chemotherapy (4 cycles of AC or 6 cycles of CMF, physician's choice) to single-agent oral capecitabine (daily for 14 days every 3 weeks for 6 cycles) in good performance status patients age 65 or older with stage I (tumors at least 1 cm in diameter) or II disease (217). While accrual to the study was slower than anticipated, 633 patients were enrolled over slightly more than 5 years. Of the patients enrolled, 70% were over the age of 70, 70% were node-positive, and 68% were HR+. Patients assigned to capecitabine were twice as likely to relapse as patients assigned to standard chemotherapy, and also twice as likely to die due to breast cancer. The standard chemotherapy was generally well tolerated, but the investigators noted that patients treated with CMF were less likely to complete their planned treatment, most often due to nonhematologic (mostly gastrointestinal) toxicities. Results of this study support administration of standard adjuvant chemotherapy, in contrast to a lessintensive regimen, in older women deemed to be at significant risk for disease recurrence who have no obvious contraindications to such treatment.

Based on the superiority to adjuvant docetaxel, doxorubicin and cyclophosphamide (TAC) over CAF in the BCIRG 001 trial (218), a number of studies have examined concurrent anthracycline and taxane regimens. ECOG 2197 compared 4 cycles of q3week AC with 4 cycles of q3week doxorubicin and docetaxel (AT) in 2,882 patients, of whom two-thirds were node-negative and 68% HR+ (219). There were no significant differences in DFS or OS for the overall study population, though a trend favored AT in patients with HR- tumors. The AT regimen was associated with a significantly higher rate (26% vs. 10%) of febrile neutropenia.

Two studies tested the TAC regimen against sequential AC followed by docetaxel (AC-T) in node-positive patients, with differing results. The NSABP B-30 study pitted 4 cycles of q3week AC followed by 4 cycles of docetaxel against 4 cycles of q3week TAC or 4 cycles of AT in 5,351 patients, of whom 75% were ER+, and just under half were premenopausal. At a median follow-up of 6 years, the sequential AC-T demonstrated superiority to the 2 briefer regimens in terms of DFS (74% vs. 69% for TAC and AT) and OS (83% vs. 79% for TAC and AT), an advantage that held up in all of the subgroups examined. In contrast, the BCIRG 005 trial demonstrated equivalent DFS and OS in 3,298 women randomized to either the same AC-T regimen or 6 cycles of TAC. The NSABP reported a higher incidence of febrile neutropenia with the sequential AC-T regimen (22% vs. 16% for TAC), while in the BCIRG study it was more common with TAC (17% vs. 8%); on neither study did patients routinely receive G-CSF support. The higher dose of docetaxel administered in the sequential arm of the BCIRG study (100 vs. 75 mg/m² with TAC) was associated with more sensory neuropathy, myalgias, and onycholysis. Of interest, premenopausal patients on the NSABP B-30 study who developed persistent amenorrhea following adjuvant chemotherapy had a 24% improvement in DFS independent of which chemotherapy regimen they received.

Results of these studies, together with CALGB 9741 and ECOG 1199 (200,201), which demonstrated superiority of either q2week or weekly paclitaxel or q3week docetaxel over the q3week paclitaxel control regimen after 4 cycles of q3week AC, and the CALGB 9344 and NSABP B-28 (197,220) studies, which first demonstrated the advantage of adding a taxane to anthracycline-based adjuvant chemotherapy in node-positive patients, suggest that current standard adjuvant chemotherapy regimen for higher risk HER2- breast cancer (see the discussion of adjuvant chemotherapy for HER2+ breast cancer in the section on biologic therapies) should be either: (1) 4 cycles of AC (or EC), preferably administered every 2 weeks (especially in ER-negative patients) with G-CSF, followed by either lower dose (80 mg/m²) weekly paclitaxel for 12 weeks, higher dose (175 mg/m²) paclitaxel every 2 weeks (also with G-CSF) or docetaxel 100 mg/m² every 3 weeks for 4 cycles; or (2) 6 cycles of TAC every 3

weeks (with G-CSF support). Given data questioning the value of incorporating an anthracycline in adjuvant chemotherapy for HER2+ patients, an ongoing study compares 6 cycles of TAC with 6 cycles of the TC regimen; until the results of that study are available, such an approach is appropriate only in patients in whom there is a clear contraindication to administration of an anthracycline (such as pre-existing impaired cardiac function).

A number of trials have investigated the addition of other chemotherapeutic agents to this anthracycline-taxane “backbone”. NSABP B-38, which has completed accrual of 4,894 node-positive patients but with no results yet reported, compares 6 cycles of TAC with 4 cycles of q2week AC followed by 4 cycles of q2week paclitaxel or 4 cycles of q2week AC followed by 4 cycles of paclitaxel and gemcitabine. The FinXX study compared the sequence of 3 cycles of docetaxel (80 mg/m²) followed by 3 cycles of CEF (T-CEF) with 3 cycles of docetaxel (60 mg/m²) and capecitabine followed by 3 cycles of CEX (in which 5-fluorouracil was replaced by capecitabine) (XT-CEX) in 1,500 women, of whom 90% were node-positive and 77% ER+. Treatment with the XT-CEX regimen was associated with modest improvements in DFS (absolute 2.5% at 5 years) and OS (2.9% at 5 years); these differences were not statistically significant, and the experimental regimen was associated with a much higher rate of early treatment discontinuation (25% vs. 4%), as well as more mucositis, diarrhea, and hand-foot dermatitis, though a lower rate of febrile neutropenia (6% vs. 12%). Exploratory analyses suggested that the experimental regimen was superior to the control regimen in patients with TNBC, in whom the recurrence rate was halved, and in patients with 4 or more positive axillary nodes. The U.S. Oncology 01062 trial treated 2,611 women, of whom 70% were node-positive and 62% HR+, with 4 cycles of q3week AC followed by either 4 cycles of docetaxel (100 mg/m²) (AC-T) or docetaxel (75 mg/m²) and capecitabine (825 mg/m² BID) (AC-TX). After a median follow-up of 5 years, the AC-TX regimen did not demonstrate statistically significant improvement in DFS (89% vs. 87% for AC-T), but did improve OS (94% vs. 92%). As in the FinXX study, patients with TNBC appeared to receive more benefit from the addition of capecitabine, as did patients whose tumors exhibited a relatively high proliferative rate (Ki67 > 10%). As expected, patients assigned to receive capecitabine experienced more mucositis, diarrhea, and hand-foot dermatitis, and required more frequent dose modifications and treatment discontinuation, but had fewer instances of febrile neutropenia. While intriguing, especially in high-risk TNBC, results from these 2 studies are not felt to be sufficient to alter the standard treatment recommendations above.

Neoadjuvant Chemotherapy

Preoperative or neoadjuvant chemotherapy (NACT) is the standard treatment for women with locally advanced, unresectable breast cancers and for women with large breast tumors who would require a mastectomy but desire an attempt at breast conservation, unless the patient is too old or frail to tolerate chemotherapy. In LABC, NACT often renders the patient resectable, and sometimes even a candidate for BCS, as well as eradicating occult metastatic disease and improving DFS and OS. In patients with resectable breast cancer, a meta-analysis of studies that compared preoperative with identical postoperative chemotherapy demonstrated equivalent DFS and OS and a significant increase in the percentage of patients able to undergo BCS, though the latter was accompanied by a slightly higher risk of locoregional recurrence (221). Updated results from one of the largest of the studies included in this analysis, the NSABP B-18 study, demonstrated DFS trends favoring preoperative chemotherapy in patients under the age of 50 and in patients who were still alive and free of disease at 5 years (222). While intriguing, these results should be considered more as hypothesis generating than for treatment guidance.

Evaluating Response To NACT

It is clear that patients with chemo-responsive disease, as indicated by achievement of a pCR—varying definitions of this endpoint are discussed below—have significantly improved outcomes compared to patients with residual invasive disease in the breast and/or axillary nodes; in the meta-analysis, pCR was associated with 52% improvements in both DFS and OS.

The optimal method to assess response to NACT is controversial. In patients with visible or palpable disease, response (or lack thereof) can often be assessed on physical examination. Sequential imaging studies by US or MRI will usually indicate whether a patient is responding or not, though occasionally clinically “stable” tumors will prove to be largely or totally replaced with fibrous tissue, but are relatively insensitive for assessing the breast and axilla for microscopic disease following resolution of any visible tumor mass or abnormal nodes (223). In clinical trials, a significant proportion of patients with clinical complete responses will prove to have residual invasive disease in the breast and/or axilla at surgery. Pilot studies evaluating the utility of positron emission tomography (PET) to assess treatment response suggest that persistence of tumor FDG avidity during NACT is associated with a low likelihood of pCR, as well as higher disease recurrence and mortality rates (224).

The initial NSABP studies (B-18 and B-27) defined pCR as the absence of invasive disease in the breast, irrespective of the presence of any residual disease in the axillary nodes (222). A retrospective analysis of patients treated at the University of Texas MD Anderson Cancer Center (MDACC) demonstrated that the presence of residual DCIS in the breast, in the absence of residual invasive disease, did not impact outcomes (DFS and OS) (129). In contrast, persistent disease in the axillary nodes is associated with higher recurrence rates, while conversion from node-positive to node-negative with NACT indicates a good prognosis (225,226). In B-27, the NSABP noted that the presence of residual disease in the axillary nodes at surgery was predictive of recurrence independent of the presence or absence of residual invasive disease in the breast (227). Based on these findings, most U.S. studies use the absence of invasive disease in the breast and axilla (ypT0/isN0) as their definition of pCR.

A recent retrospective analysis of several NACT studies performed by German investigators questions the validity of this definition (228). Correlating tumor response at surgery to long-term outcome in 6,377 patients treated on 7 prospective trials with a median post-op follow-up of 46 months, the absence of either invasive or *in situ* disease in the breast and negative lymph nodes (ypT0N0), which was achieved in 15.0% of patients, was associated with the greatest improvement in DFS (55%) compared to patients who did not achieve this level of response. Classifying patients with residual *in situ* disease, involved lymph nodes and/or residual invasive disease less than 1 mm in diameter (ypT1mic) as pCRs reduced the DFS advantage, and patients in those categories did not appear to have improved DFS or OS compared to patients with more extensive residual disease. Also of interest, the correlation between achieving pCR (ypT0N0) with NACT and prognosis (DFS and OS) was apparent only in patients with more aggressive cancers, including TNBC, ER-/HER2+ and atypical ER+ (luminal B) cancers, but not in typical ER+ (luminal A) and ER+/HER2+ cancers. Patients with less-aggressive cancers were less likely to obtain a pCR, but had similar outcomes whether or not they achieved one, while patients with more-aggressive cancers were both more likely to achieve a pCR and to recur early if they did not. In TNBC, this observation has been referred to the “triple-negative paradox” (229).

The German data present response to NACT as a black/white contrast—a patient either achieves a pCR or is counted as a treatment failure. Other analyses suggest that extent of residual disease after NACT remains prognostic in the absence of a pCR. European investigators have used a number of scoring systems,

the best known of which is the Miller/Payne grading system, to assess post-NACT pathologic specimens for both residual disease and chemotherapy response, the results of which have been shown to correlate with DFS and OS (230). Symmans et al. at MDACC also assessed pathologic findings after anthracycline- and taxane-based NACT and found that the size and cellularity of residual invasive disease in the breast and number and size of metastatic deposits in the axillary nodes were predictive of distant recurrence (231). These variables are incorporated into a formula called the patient's Residual Cancer Burden (RCB). Of interest, patients with minimal residual disease (RCB-I) appear to be at no greater risk of distant disease recurrence than patients with a pCR (RCB-0), while patients with more extensive residual disease (RCB-II and -III) are at much greater risk of recurrence, especially if their tumor is HR-. RCB analyses have been incorporated into a number of NACT studies, both to stratify non-pCR responses and to validate this methodology.

NACT Regimens

A general principle regarding NACT regimens is that chemotherapeutic agents that have proven effectiveness in the adjuvant setting should have similar efficacy against disease in the breast and axillary nodes as well as occult metastatic disease in the neoadjuvant setting. Thus, there is no reason to use different regimens based on when the chemotherapy is given with respect to surgery. The choice of specific chemotherapy drugs and regimens should be based on our understanding of therapy response as related to tumor biology and patient subsets such as ER+/HER2-, HER2+, and TNBC.

Given the high-risk factors present in most patients who are offered NACT—tumor size, clinically apparent axillary lymph node involvement, more aggressive subtypes such as HER2+ or TNBC, and in some cases evidence of extensive disease in the breast and/or regional lymph nodes—in most patients, sequential administration of both an anthracycline and a taxane is indicated and is associated with higher pCR rates than AC alone or concurrent AT (232). For example, in the NSABP B-27 trial, 2,411 patients received 4 cycles of q3week AC and were randomized to receive either no further chemotherapy, 4 cycles of neoadjuvant q3week docetaxel (100 mg/m²) or surgery followed by 4 cycles of docetaxel. The addition of neoadjuvant docetaxel doubled the pCR rate from 13% to 26%, and while this did not translate into improvements in DFS and OS, the subset of patients who had a partial clinical response to the 4 cycles of AC did have improved outcomes with the addition of neoadjuvant docetaxel. In the Aberdeen study, switching patients who were responding after 4 cycles of an anthracycline-based regimen to docetaxel improved not only the pCR rate (to 34%, compared to 16% in patients who continued the anthracycline-based regimen) and the BCS rate (67% vs. 48%), but also OS at 3 years.

pCR rates for sequential therapy with an anthracycline and a taxane depend on the tumor type, ranging from as low as 5% for low-grade ER+/HER2- (luminal A) cancers to 34% for basal-like TNBC to 55% for HER2+ (with concurrent trastuzumab). Though the use of dose-dense NACT is based largely on data from the adjuvant setting, there are a few studies that demonstrate higher pCR rates with dose-dense chemotherapy in the preoperative setting (233,234). Thus far, the addition of other chemotherapeutic agents to this regimen—such as capecitabine with the docetaxel in the GeparQuattro trial (235), or either capecitabine or gemcitabine with the docetaxel in the NSABP B-40 trial (192)—has failed to improve pCR rates.

Based on similarities in clinical and pathologic features, and gene expression patterns between cancers that develop in women who carry *BRCA1* mutations and sporadic TNBC, and data demonstrating suggesting high pCR rates in patients with *BRCA*-related cancers treated with platinum analogs (236),

there is interest in studying the addition of this class of agents to standard NACT in TNBC.

What to do for patients who are not responding to NACT is unknown. In the Aberdeen trial, patients not responding after 4 cycles of the anthracycline-based regimen were switched to docetaxel, and while 55% had a clinical response to the taxane, their pCR rate was only 2%, and their 3-year survival was markedly inferior to the responsive patients. In the GeparTrio trial, patients who did not respond with at least a 50% reduction in tumor size after 2 cycles of TAC were randomly assigned to either 4 more cycles of TAC or 4 cycles of vinorelbine and capecitabine (NX) every 21 days. While both groups of patients had similar clinical response (51%) and pCR (5% to 6%) rates, a recent update of the trial reported that patients switched to NX demonstrated significant (41%) improvement in DFS compared to patients who continued on TAC (GGG). Meanwhile, patients responding after 2 cycles of TAC were randomized to 4 or 6 more cycles of the same regimen, and while the longer treatment duration had only a modest impact on the pCR rate (24% vs. 21%), it did result in significant improvement in DFS.

Treatment for patients who go to surgery after NACT and are found to have significant residual disease is based on their tumor type. Patients with ER+ tumors typically receive adjuvant endocrine therapy, while patients with HER2+ cancers receive trastuzumab. There is no evidence that administration of additional chemotherapy, sometimes referred to “adjuvant after neoadjuvant”, in a patient who has received both an anthracycline and a taxane in the preoperative setting, will reduce recurrences in patients with residual TNBC, though the GeparTrio data cited above offer a glimmer of hope. There is also interest in testing novel targeted (biologic) agents in these patients.

Chemotherapy for Metastatic Breast Cancer

As noted previously, chemotherapy is appropriate treatment for patients with metastatic breast cancer (MBC) that is hormone-insensitive (ER- and PR-) or refractory (having progressed on one or more endocrine therapies), displays aggressive biology (rapid disease progression or early recurrence following adjuvant or neoadjuvant therapy), or is associated with significant symptoms or evidence of extensive or rapidly progressive involvement of vital organs (most often the liver or lungs), which is referred to as visceral crisis. Choice of chemotherapeutic agent or combination of agents depends upon the extent and biology of the patient's disease, her age, performance status and comorbid medical conditions, timing and extent of prior treatment, and her doctor's willingness to accept the risks of various toxicities as a tradeoff for antitumor efficacy, with the understanding that her condition is not curable and that differences in survival with various approaches are modest at best.

Combinations versus Sequential Single-Agent Chemotherapy

A meta-analysis published in 2005 reported significant, though relatively modest, improvements in overall response rate (ORR), PFS, and OS with administration of combination chemotherapy compared to single-agent chemotherapy in MBC, at the cost of increased hematologic and gastrointestinal toxicities (237). However, the studies included in that analysis predated approval of many of the active classes of single agents currently available. The general consensus among oncologists is that combination chemotherapy regimens often produce higher ORR and modest increases in PFS compared with single-agent chemotherapy, but without meaningful improvements in OS (this generalization

is not intended to cover the addition of HER2-targeted agents in patients with HER2+ cancers, which have clearly shown significant improvements in OS; these are covered in the section on biologic therapies). A few more recent randomized studies comparing novel chemotherapy combinations to a single agent have demonstrated improvement in OS as well as ORR and PFS, but have been faulted for the absence of crossover of patients assigned to the single agent and/or inadequate documentation as to subsequent treatment received. On the other hand, patients who require rapid disease response due to symptoms or life-threatening visceral involvement are more likely to respond to a combination regimen.

Combination Regimens

Combination regimens worth considering in the appropriate clinical setting include doxorubicin (or epirubicin) and cyclophosphamide; Anthracyclines have the best single-agent activity in chemotherapy-naïve patients with MBC, and older studies demonstrated that the addition of cyclophosphamide increased that activity, at the cost of greater (primarily hematologic) toxicity. Patients who received an anthracycline in the adjuvant setting are generally not considered candidates to receive the same or a similar agent for metastatic disease unless at least 12 months elapsed from completion of their prior anthracycline-based treatment to disease recurrence; even then, administration of a standard anthracycline will be limited by the increasing risk of cardiotoxicity when the cumulative doxorubicin dose crosses 450 mg/m². The addition of the cardioprotectant dexrazoxane in a 10:1 ratio to the dose of doxorubicin being administered, after response to the anthracycline-based regimen is documented, may allow more prolonged treatment with the regimen, with cardiac monitoring recommended every 2 cycles once the cumulative dose exceeds 450 mg/m². Another alternative is substitution of pegylated liposome-encapsulated doxorubicin (PLD), which is associated with less cardiotoxicity than the standard form of the drug. A multicenter study of PLD 35 mg/m² and cyclophosphamide 600 mg/m² every 3 weeks as first-line chemotherapy in patients with MBC who had received an anthracycline-containing regimen in the adjuvant setting greater than 12 months earlier demonstrated an ORR of 38%, with another 33% of patients achieving stable disease (SD) for at least 6 months, a median TTP of 12.2 months and median OS of 16.5 months.

Anthracycline and taxane combinations: Given the activity of taxanes in untreated and anthracycline-pretreated MBC, several studies have compared anthracycline-taxane combinations (doxorubicin or epirubicin with paclitaxel or docetaxel, AT or ET) with nontaxane combinations like AC or CAF. A meta-analysis of these studies demonstrated that the taxane-based combinations were associated with a higher ORR (57% vs. 46%) and a modest improvement in PFS, but no significant improvement in survival. The taxane-based combinations were associated with higher rates of febrile neutropenia, and concurrent paclitaxel and doxorubicin have also been linked to increased cardiotoxicity.

Taxanes and other agents. The addition of capecitabine (1,250 mg/m²) to docetaxel (100 mg/m² as a single agent; 75 mg/m² when combined with capecitabine) in patients with anthracycline-refractory MBC improved the ORR (from 30% to 42%), median TTP (from 4.2 to 6.1 months) and median OS (from 11.5 to 14.2 months), at the cost of increased mucositis, diarrhea, and hand-foot dermatitis (238). This study has been criticized for the low percentage of patients assigned to single-agent docetaxel who received any subsequent chemotherapy, including capecitabine. Subsequent single-arm studies have suggested better tolerance with lower doses of capecitabine or substitution of weekly paclitaxel for the q3week docetaxel (239).

The addition of gemcitabine 1,250 mg/m² on days 1 and 8 to paclitaxel 175 mg/m² on day 1 every 3 weeks also improved ORR (26% to 41%), median TTP (4 to 6 months), and median

OS (15.8 to 18.5 months), at the cost of an increase in neutropenia, rare cases of febrile neutropenia, and fatigue (240). Again, assessment of this study was hampered by the failure to administer gemcitabine to a significant fraction of patients who progressed on single-agent paclitaxel. In a subsequent randomized study, the combination of gemcitabine and docetaxel failed to demonstrate superiority to the sequence of docetaxel followed by gemcitabine (241).

The addition of the VEGF-targeted agent bevacizumab to weekly paclitaxel and other chemotherapeutic agents, including docetaxel, is addressed in the biologic therapies section.

Other combinations. The combination of the epothilone ixabepilone 40 mg/m² q3weeks and capecitabine was compared to single-agent capecitabine in patients with MBC considered refractory to anthracyclines and taxanes (242). The addition of ixabepilone increased the ORR from 14% to 35%, with the largest impact on patients with TNBC (11% to 35%) and patients who had relapsed within 12 months of receiving both an anthracycline and a taxane in the adjuvant setting (17% to 68%), and median PFS from 4.1 to 5.7 months, but did not improve median OS, and was associated with increased hematologic (especially neutropenia) and nonhematologic (neuropathy, nausea/vomiting, myalgias and alopecia) toxicities.

The platinum analogs, cisplatin and carboplatin, have been studied in combination with a variety of agents, including the taxanes and gemcitabine. This class of agents may have greater activity in patients with TNBC, but whether they can prolong survival in these patients compared to single agents or other combinations is unclear.

Metronomic chemotherapy, most often consisting of daily low-dose oral cyclophosphamide and twice-weekly low-dose methotrexate, is generally well tolerated, but has had varying results in patients with advanced breast cancer. One recent study in 41 patients, of whom 16 had had no prior chemotherapy for MBC, demonstrated an ORR of 17% and median TTP of only 10 weeks (202).

Single-Agent Chemotherapy

A large number of cytotoxic agents have demonstrated some degree of antitumor efficacy in BC. There is no evidence that order of administration influences survival, though ORR predictably falls with successive lines of treatment. Relatively few have been compared head-to-head, and, despite ongoing efforts to develop such testing, there is no reliable chemosensitivity assay to help guide treatment selection. Thus, decisions as to which agents to try and in which order are often based more on patient preferences regarding route and schedule of administration and relative toxicities than on likelihood of response. Cost factors may also play a role.

Among the Active Classes of Agents

Anthracyclines remain the most effective class of agents, with ORR of 35% to 50% in patients who are chemotherapy naïve or at least 12 months out from anthracycline-based adjuvant chemotherapy. As with most classes of agents, they are clearly less effective when administered as second- or subsequent-line therapy. As discussed above, cumulative doses of doxorubicin exceeding 450 mg/m² are associated with increasing risk of cardiomyopathy, a concern that can be addressed by adding dexrazoxane or substituting PLD. In a phase III study, PLD 50 mg/m² q4weeks demonstrated equivalent PFS and OS compared to standard doxorubicin 60 mg/m², with less cardiotoxicity, alopecia, nausea, vomiting and neutropenia, but greater mucositis and hand-foot dermatitis.

Taxanes, including paclitaxel, docetaxel, and nanoparticle albumin-bound paclitaxel (nab-paclitaxel), show significant activity against both chemotherapy naïve and

anthracycline-pretreated MBC. In a meta-analysis of studies comparing single-agent taxanes to anthracyclines, the ORR was slightly higher for the anthracyclines (38% vs. 33%), but PFS and OS were equivalent (243). However, in these older studies, paclitaxel was administered q3weeks, while a meta-analysis of studies comparing weekly to q3week paclitaxel demonstrated a survival benefit for the weekly schedule (244). While the frequency and severity of neuropathy may be worse with the weekly schedule (199), this toxicity can be reduced by giving the patient every fourth week off, thus administering the drug at 80 to 100 mg/m² on days 1, 8, and 15 every 28 days. In contrast, weekly docetaxel appears to be no more effective and potentially more toxic than q3week docetaxel. A trial that compared q3week paclitaxel (175 mg/m²) to docetaxel (100 mg/m²) demonstrated slight improvements in median PFS and OS for docetaxel, along with significantly more severe hematologic and nonhematologic toxicities (245). Docetaxel has not been directly compared to weekly paclitaxel in MBC. Of interest, the 2 drugs do not appear to be completely cross-resistant, suggesting that a trial of the alternate taxane, preferably administered on a different schedule, can be considered in patients who relapse at least 12 months after completing a taxane-based adjuvant regimen (246).

The advantage of administering nab-paclitaxel is the elimination of polyethoxylated castor oil (Cremaphor), which is required to maintain standard paclitaxel in solution and appears to be responsible for most of the hypersensitivity reactions seen with “solvent-based” paclitaxel, thus permitting the elimination of corticosteroids and antihistamines from the premedication regimen. In theory, albumin binding might also facilitate penetration of the drug through the endothelial layer into cancer tumors. A phase III study comparing nab-paclitaxel 260 mg/m² with paclitaxel 175 mg/m² q3weeks demonstrated a higher ORR (33% vs. 19%), prolonged TTP (23 vs. 16.9 weeks) and a trend favoring prolonged OS for the nab-paclitaxel, with a lower incidence of grade 4 neutropenia despite the higher dose (247). No study has yet reported a comparison between nab-paclitaxel and a weekly standard paclitaxel regimen.

Antimetabolites: The oral 5-fluorouracil pro-drug capecitabine, more often administered at doses ranging from 1,500 mg BID to 1,000 mg/m² BID than at the approved dose of 1,250 mg/m² BID for 14 days q3weeks (248), yields an ORR of approximately 30% as first-line chemotherapy, and is also active as salvage therapy, though likely less so in patients with more-aggressive tumors such as TNBC. While it can cause diarrhea and hand-foot dermatitis, it seldom causes alopecia or myelosuppression. Alternative schedules, such as alternating one week on and one week off treatment, are being investigated to reduce toxicity while retaining antitumor efficacy.

The nucleoside analog gemcitabine, typically administered at 1,000 to 1,250 mg/m² IV days 1 and 8 q3weeks, is an active agent in first-line MBC (249) and is also generally well tolerated, with mild nausea and infrequent alopecia, though it can cause myelosuppression, especially thrombocytopenia, in previously treated patients, as well as fatigue, rashes, and rare serious hepatic and pulmonary toxicities.

Tubulin-targeted agents: The antimicrotubule agent vinorelbine, typically administered at 25 mg/m² IV days 1 and 8 q3weeks, has been associated with ORRs of 25% to 45% as a single agent in the first-line setting (250), and seldom causes nausea, diarrhea, or hair loss. It can cause myelosuppression, peripheral and sometimes autonomic neuropathy, more often in diabetics and patients with prior taxane exposure, and occasionally painful vasospasm when injected into a peripheral vein, which is why most oncologists prefer to administer it via a central line.

Oral etoposide 50 mg/m² daily for 21 days q4weeks has been reported to yield ORRs of up to 30% as second- or

subsequent-line therapy, but can cause significant hematologic and gastrointestinal toxicities.

The epothilone ixabepilone, which is derived from the soil-dwelling gram negative bacterium *Sorangium cellulosum* and interferes with microtubule disassembly by binding to tubulin at different sites than the taxanes, is typically administered at 40 mg/m² IV q3weeks. As a single agent in patients who were refractory to anthracyclines, taxanes, and capecitabine, it induced objective responses in 12.4% of patients and stable disease lasting at least 6 months in another 18.6%, while causing neutropenia, mild to moderate nausea, myalgias, fatigue, and progressive neuropathy (including grade 3 to 4 neuropathy in 14% of patients) (251).

The most recently approved chemotherapeutic agent for the treatment of MBC is eribulin, a fully synthesized analogue of the marine sponge natural product halichondrin B, which interferes with microtubule assembly necessary for formation of the mitotic spindle. In a phase III study that compared eribulin 1.4 mg/m² IV days 1 and 8 q3weeks with other chemotherapy of the physician's and patient's choice in heavily pretreated patients with MBC, patients randomized to eribulin had superior median OS (13.1 vs. 10.6 months) (252). Toxicities of the novel agent were primarily neutropenia and peripheral neuropathy.

Drugs with modest single-agent activity reported in MBC include pemetrexed, irinotecan, cisplatin, carboplatin, and cyclophosphamide.

Duration of Treatment

The optimal duration of treatment with chemotherapy in MBC is unknown. In general, studies of more prolonged administration of chemotherapy have demonstrated prolongation of TTP but little or no improvement in OS, often associated with increased toxicity and inferior quality of life. A meta-analysis of 11 trials, which compared fixed duration chemotherapy with treatment to disease progression, confirmed prolongation of PFS with a modest increase in OS. In practice, treatment is often administered until a response plateau is reached (based on imaging studies or tumor marker), the development of bothersome cumulative toxicities, or the patient requests a treatment break. In patients with HR+ disease, an effort to delay disease progression by initiating some novel (to the patient) form of endocrine therapy is reasonable, though this is not supported by any objective data. Whether to resume chemotherapy as soon as there is evidence of disease progression or to wait until the patient begins to have symptoms is not known, and best left to a joint decision between the patient and her physician.

ENDOCRINE THERAPY

The role of endocrine therapy has grown significantly over the past several years as both our understanding of breast cancer has matured and as new therapeutic options have developed. It has become increasingly clear that endocrine therapy is the backbone of treatment for hormonally responsive breast cancer, independent of stage.

Adjuvant Endocrine Therapy

Perhaps no data set has been more instructive in helping to define benefit of adjuvant hormonal therapy than the meta-analysis generated by the EBCTCG (253). One of the principles appreciated through this Overview analysis is that the proportional benefit of a given treatment is constant through risk groups (e.g., stage) and that the absolute benefit changes based on the estimated risk of systemic recurrence. For instance, if hormonal therapy

decreases the risk of cancer recurrence by 30% in a given individual, the absolute benefit would be 3% if the 10-year risk of relapse were 10%, but 18% if the 10-year risk of relapse were 60%. This concept of proportional and absolute benefit from adjuvant therapy is a guiding principle when women are counseled regarding treatment options in the adjuvant setting.

Expression of the ER or the PR is predictive of response to hormonal therapy. Therefore, essentially any woman with invasive breast cancer should receive adjuvant hormonal therapy if their tumor is ER+ and/or PR+. Conversely, hormonal therapy is inappropriate in the ER-/PR-setting. The choices for treatment and duration of therapy continue to be the subject of active investigation.

Tamoxifen was the first hormonal agent used in the adjuvant setting for breast cancer (254,255). As a selective estrogen receptor modulator (SERM), tamoxifen has differential effects on various tissues. While tamoxifen may achieve its beneficial effect in the treatment of breast cancer through multiple means, the principal mode of action appears to be through competitive binding to the ER. By preventing estrogen binding, translocation and nuclear binding of the ER is inhibited, altering transcriptional and posttranscriptional events mediated by the receptor. The antagonistic properties of tamoxifen toward breast cancer are contrasted against its agonistic effects on other tissues, such as the bone and uterus. Tamoxifen, like estrogen, improves bone mineral density in postmenopausal women and is a risk factor for endometrial cancer. Tamoxifen may negatively affect bone density in premenopausal women. The risk of endometrial cancer with the use of tamoxifen is estimated at two- to three-fold over the general population risk, though the risk is likely lower in premenopausal women and perhaps close to the general population risk as demonstrated in the NSABP P-1 trial (256). It is recommended that women on tamoxifen follow general guidelines for gynecologic screening and follow-up, but, importantly, report any menstrual changes, dysfunctional uterine bleeding, or other symptoms to their gynecologist. Women should discuss the use of tamoxifen with their gynecologist to ensure that they are being properly evaluated.

Another important risk associated with tamoxifen is that of venous thrombosis. While perhaps less so in premenopausal women, as demonstrated by the NSABP P-1 trial, tamoxifen has an approximate two-fold increase in risk for deep venous thrombosis (DVT) over the general population risk (256). This risk is sometimes described as similar to that associated with the use of oral contraceptives and may influence choice of hormonal therapy in the postmenopausal setting.

Other potential side effects of tamoxifen include hot flashes, weight gain, mood changes, increased vaginal discharge, cataracts, and rarely retinal abnormalities. Several studies have suggested an increase in risk of stroke with tamoxifen. Tamoxifen can increase fertility by increasing ovarian stimulation and is a teratogen, and is therefore contraindicated during pregnancy. Moreover, premenopausal women on tamoxifen need to ensure appropriate contraception as it is possible to become pregnant while on this medication.

Benefit from the use of tamoxifen in the adjuvant setting has been demonstrated in multiple clinical trials. The Scottish tamoxifen trial published in *The Lancet* in 1987 evaluated the use of tamoxifen 20 mg daily for 5 years in 1,312 premenopausal node-negative or postmenopausal women with any nodal status (254). This trial defined tamoxifen as an effective adjuvant in node-negative and node-positive patients as well as in the pre- and postmenopausal setting, and is considered a landmark trial. NSABP B-14 evaluated the use of tamoxifen versus placebo for 5 years in 869 premenopausal and 1,949 postmenopausal women with node-negative breast cancer, demonstrating statistically significant improvement in DFS and OS with the use of tamoxifen (255).

Although multiple dosing strategies have been tried, there is no demonstrated dose response curve between 20 and 40 mg. The recent EBCTCG report on adjuvant tamoxifen showed a trend toward improved recurrence-free survival with higher doses but no benefit in mortality (257). Thus, 20 mg per day is the recommended dose currently. Five years of tamoxifen has been considered standard, though recent data suggest that continuing tamoxifen through 10 years may further improve DFS and OS. Longer duration, therefore, can be considered, especially in higher-risk women (258,259). Therefore 5 years of treatment is recommended. The EBCTCG, which included more than 10,000 women with ER+ breast cancer, showed that treatment with 5 years of tamoxifen resulted in an improvement in DFS and OS of 39% and 30%, respectively, at 15 years (257).

Another decision-making tool in women who have an option of endocrine therapy or chemotherapy is the Oncotype DX assay. Using 668 available paraffin blocks from the B-14 trial, Paik et al. evaluated 16 cancer related genes to define an algorithm to assess risk of recurrence at 10 years (70). By creating a continuum of recurrence score based on gene expression analysis, 3 risk groups were broken out: low risk, intermediate risk, and high risk. Looking at this group of node-negative HR+ women, all of whom received tamoxifen, individuals in the low-risk category did not appear to benefit from the addition of chemotherapy to tamoxifen and are likely best served by hormonal therapy alone. Women in the high-risk group likely benefit from the addition of chemotherapy to hormonal therapy. Whether hormonal therapy alone is adequate in the intermediate-risk group is less clear and is currently being studied in a prospective randomized trial. Gene and protein expression prognostic and predictive models will continue to be developed to aid in defining appropriate therapy across risk groups and will complement established prognostic and predictive factors such as tumor size, grade, receptor status, nodal involvement, and HER2 overexpression.

While tamoxifen remains the only established hormonal agent in premenopausal women, choices in the postmenopausal setting have increased through the study and development of highly selective aromatase inhibitors. Initially, through the study of first generation aromatase inhibitors such as aminoglutethimide, these agents were found to be effective therapy for postmenopausal women. Aromatase inhibitors block estrogen production by preventing conversion of androgens produced by the adrenal gland (such as androstenedione) to estrogens, such as estrone, which is later converted to estradiol. This block occurs in the breast as well as in peripheral tissues, such as adipose tissue. The resulting decrease in circulating estrogen has been demonstrated through multiple clinical trials to be effective treatment for receptor-positive breast cancer. Of the 3 commercially available aromatase inhibitors, anastrozole and letrozole are nonsteroidal, whereas exemestane is a steroidal aromatase inhibitor. There are currently no demonstrable differences in efficacy or toxicity between these 3 products. Toxicities of aromatase inhibitors commonly include hot flashes and joint or muscle aches. Unlike tamoxifen, aromatase inhibitors can contribute to osteopenia and osteoporosis with an increased incidence of fractures, and therefore bone density should be followed carefully in women receiving these medicines. Other possible side effects include hypertension, gastrointestinal disturbance, depression, urovaginal symptoms, and possibly cardiac events. Aromatase inhibitors are not associated with an increased risk of endometrial cancer and have a lower risk for DVT compared to tamoxifen (260).

Several studies have demonstrated the efficacy of aromatase inhibitors in the adjuvant setting. The ATAC trial, one of the largest prospective adjuvant trials in breast cancer, randomized 9,300 postmenopausal women to tamoxifen, anastrozole, or the

combination (261). With a median follow-up of 120 months, there was a statistically significant benefit in DFS to anastrozole over tamoxifen with a hazard ratio of 0.91 in ER+ patients. There was no benefit to the combination. The Intergroup Exemestane Study (IES) randomized 4,700 postmenopausal women after 2 to 3 years of adjuvant tamoxifen to receive either tamoxifen or exemestane to complete 5 years of adjuvant therapy (262). With a median follow-up of 91 months, there was a statistically significant benefit in DFS for the inclusion of the aromatase inhibitor with a hazard ratio of 0.81, and a modest benefit to OS with a hazard ratio of 0.86. The MA17 initially published by Goss et al. randomized patients who had completed 5 years of adjuvant tamoxifen to 5 additional years of letrozole or placebo. After a median follow-up of 64 months, there was a statistically significant benefit to the inclusion of an aromatase inhibitor with a hazard ratio of 0.52 for DFS and 0.61 for OS (263). One important observation of this trial is that after unblinding, a large group of women assigned to placebo crossed over to letrozole. Despite an average delay of 2.8 years, treatment with letrozole after 5 years of tamoxifen significantly reduced the risk of recurrence. The Breast International Group (BIG) 1 to 98 study prospectively randomized 8,010 postmenopausal women with HR+ breast cancer to either tamoxifen for 5 years, letrozole for 5 years, tamoxifen for 2 years switching to letrozole for 3 years, or letrozole for 2 years switching to tamoxifen for 3 years. After a median follow-up of 26 months, the 2 groups that were assigned letrozole initially had a statistically significant improvement in DFS with a hazard ratio of 0.81 (264). A follow-up analysis of this trial published in 2009 showed after 71 months of follow-up that 5 years of letrozole compared to 5 years of tamoxifen reduced the risk of recurrence with a hazard ratio of 0.88; however, there was no difference between the sequential groups and continuous letrozole (265). Finally, the TEAM trial randomized more than 9,700 women to 5 years of exemestane or 2 to 2.5 years of tamoxifen followed by exemestane to complete 5 years. After 5 years of follow-up, DFS was similar in both groups (266).

Based on these trials, it is recommended that all postmenopausal women receiving adjuvant hormonal therapy receive at least 2 to 3 years of an aromatase inhibitor unless contraindicated, and treatment with an AI beyond 5 years is the subject of current investigation.

The degree of benefit and choice of hormonal therapy may be further influenced by primary tumor characteristics. The level of expression and potentially the relative expression of ER and PR positivity in breast cancer cells may be predictive of the responsiveness of the tumor to hormonal manipulation (267). It is therefore important to incorporate the degree of ER and PR positivity into adjuvant therapy decisions. Going against the conventional understanding of how the ER and PR expression predicts for benefit from endocrine therapy, the recent EBCTCG report on tamoxifen has shown uniform benefit in ER+ tumors regardless of the level of expression and no benefit in ER-tumors independent of PR expression (257). This remains an area of active investigation. The differential benefit to tamoxifen and aromatase inhibitors in the postmenopausal ER+/HER2+ setting also requires further study.

Ovarian Ablation

Ovarian ablation (OA) has long been explored as a therapeutic option for women with breast cancer. As the ovaries are the major source for estrogen, silencing the ovaries via surgical oophorectomy, radiotherapy, or the use of GnRH analogues may provide a benefit, although controversy continues as to its role in modern breast cancer management. The EBCTG overview on OA included 12 trials that compared OA by surgery or

radiation to control and encompassed 2012 women with early breast cancer. The meta-analysis concluded that OA was associated with both DFS and OS advantages when compared to observation. At 15 years, 52% were alive in those who underwent OA, compared to 46% who did not ($p = 0.001$), and 45% were disease-free, compared to 39% ($p = 0.0007$). When trials using OA versus chemotherapy following breast surgery were analyzed; however, the benefits of OA were more modest and did not achieve statistical significance. Despite these findings, OA cannot be considered equivalent to chemotherapy as these trials compared OA to chemotherapy that is considered inferior to modern adjuvant chemotherapy. Still, among premenopausal women who do not receive chemotherapy, OA may play a significant role in management.

Since the meta-analysis, several results have been published in this area. The International Breast Cancer Study Group (IBCSG) Trial VIII randomized 1,063 women with node-negative breast cancer to chemotherapy (CMF) versus Goserelin (G) versus CMF followed by G. Of note, 30% of women in this study had ER-disease. Restricting the analysis to women with ER+ disease, after median follow-up of 12.1 years, sequential therapy improved DFS compared to either treatment modality alone (DFS 77%, 68%, and 69% for CMF-G, G and CMF respectively) (269). This benefit to OA is not, however, consistently seen. Arriagada et al. randomized 926 women who had completed surgery and chemotherapy to OA (by ovarian radiation or with triptorelin) or observation (270). Ninety percent of women had positive nodes and 77% received anthracycline-based chemotherapy. Of the cohort, 63% were ER+. Estimated 10-year DFS and OS were similar in both groups, though subgroup analysis suggested that women under 40 and who had ER+ diseases benefited significantly. A plausible explanation for this observation is that younger women are more likely to recover ovarian function after chemotherapy and therefore more likely to benefit from ovarian suppression.

The ZIPP trial randomized 2,700 women to 2 years of tamoxifen (T), Goserelin (G), T+G or observation in a 2×2 factorial design. At 12 years of follow-up, the addition of G to tamoxifen versus the group receiving tamoxifen alone resulted in a small, nonstatistically significant reduction in the risk of recurrence (2.8%) (271).

The Intergroup 0101 trial examined the effect of adding OA (Goserelin) or OA and tamoxifen to anthracycline-based chemotherapy. Fifteen hundred women received 6 cycles of CAF chemotherapy alone or followed by 5 years of OA (CAF-Z) or CAF followed by 5 years of OA and tamoxifen (CAF-ZT). After 9.6 years of follow-up, there was no benefit to the addition of Z to chemotherapy. The addition of tamoxifen improved DFS but not OS (272).

The Austrian Breast Cancer Study Group randomized 1,800 premenopausal women to 3 years of Goserelin and either tamoxifen or Anastrozole with or without Zoledronic acid. After a median follow-up of 62 months, there was no difference between tamoxifen and anastrozole (DFS, 88% vs. 87%, respectively) (273). Surprisingly, it was noted that the addition of Zoledronic acid reduced the risk of recurrence by 35%. Even though none of these women received chemotherapy and despite the fact that about one-third in each group had node-positive disease, these recurrence rates are surprisingly low. For women with contraindication to chemotherapy or women who do not desire it, combining OA with tamoxifen or an aromatase inhibitor could be an effective alternative.

Contemporary trials will hopefully provide more guidance as to the role of OA in women with hormone-positive breast cancer. This is an especially important issue given the marginal benefits of chemotherapy in women with ER+ breast cancer and the availability of anti-estrogen endocrine therapy. Whether OA adds an additional benefit to endocrine therapy remains a question not sufficiently addressed.

Endocrine Therapy in Metastatic Breast Cancer

Hormonal therapy is optimal initial therapy in the setting of stage IV HR+ breast cancer unless aggressive recurrence mandates chemotherapy to maximize time to response in order to avert impending organ failure (e.g., significant hepatic metastasis). Options in the premenopausal setting include ovarian suppression with or without the addition of tamoxifen or an aromatase inhibitor, or even tamoxifen alone. In the postmenopausal setting, tamoxifen or aromatase inhibitors are effective options; however, more recent data have demonstrated improved outcome when fulvestrant is used as initial therapy as compared to an AI. Fulvestrant is a pure anti-estrogen approved for use in the postmenopausal setting and is given by monthly intramuscular injection. Data from the FIRST trial demonstrated a significantly improved TTP when 205 women were randomized to first-line fulvestrant vs. anastrozole (23.4 vs. 13.1 months) and both treatments were well tolerated (274). Aromatase inhibitors remain a good option for first-line therapy and have been clearly shown to be superior to tamoxifen. A meta-analysis of more than 8,500 patients treated with either first-line AI or tamoxifen showed a significant survival benefit favoring AI (275).

Hormonal resistance eventually evolves over time, necessitating the use of chemotherapy for cancer control. The mechanisms behind the evolution of hormonal resistance and strategies to re-induce hormonal sensitivity in stage IV breast cancer continue to be actively investigated. A recently published study looking at reversing hormonal resistance with the addition of everolimus, an mTOR inhibitor, or placebo to second-line endocrine therapy with Exemetane demonstrated a significant improvement of PFS from 3 to 7 months in favor of everolimus (276).

In the case of HER2+ metastatic breast cancer, women with HR+ tumors without aggressive disease who may not require first-line treatment with chemotherapy and trastuzumab, the combination of an aromatase inhibitor with anti-HER2 targeted therapy has improved PFS when compared to endocrine therapy alone (188,189).

Neoadjuvant Endocrine Therapy

As in the adjuvant and metastatic setting, hormonal therapy can also be beneficial for women presenting with. If chemotherapy is not being employed, neoadjuvant (preoperative) hormonal therapy in the hormonally positive setting can be effective in increasing the ability to completely surgically resect the primary tumor in locally advanced disease as well as in increasing the chances for BCS. Studies suggest that neoadjuvant aromatase inhibitors can be equally as effective as chemotherapy with comparable response rates and rates of breast conservation (114,277). In postmenopausal women, aromatase inhibitors appear to be superior to tamoxifen (278).

Endocrine Therapy for Prevention

The use of tamoxifen in early adjuvant trials appeared to have the benefit of decreasing the risk of second primary breast tumors. In addition, tamoxifen in the NSABP B-24 trial has demonstrated a decreased risk of invasive and *in situ* disease in women with a history of DCIS (87). Based on these findings, the NSABP has studied the use of tamoxifen in high-risk women. Requiring a Gail model risk for developing breast cancer over 5 years of at least 1.66%, the NSABP randomized over 13,000 high-risk women 35 years of age or older to receive tamoxifen or placebo (256). After a median follow-up of 69 months, tamoxifen decreased the risk of breast cancer by approximately 50%. Women with ADH, which, like LCIS, is a risk factor for

subsequent breast cancer, had the greatest benefit for breast cancer risk reduction of 86%. The incorporation of tamoxifen as a risk reduction strategy has been limited, however, based on potential toxicity and on the modest absolute benefit it likely provides. For example, if a woman has a risk for developing breast cancer of 1% per year, the absolute benefit of tamoxifen as risk reduction would be 0.5% per year. A meta-analysis of 4 prevention trials utilizing tamoxifen in normal or higher-risk women showed a 38% reduction in the incidence of invasive breast cancer. Only the rate of ER+ breast cancer was reduced. The risk of endometrial cancer was increased by a factor of 2.4, and the risk of thromboembolic events was increased by 1.9. Importantly, there was no detectable improvement in overall mortality or breast cancer-specific mortality rates (279).

To maintain efficacy and decrease toxicity, the NSABP P-2 trial (STAR trial) studied the use of tamoxifen or another SERM, raloxifene, as prevention for high-risk postmenopausal women. Initially published in 2006, raloxifene appeared similar to tamoxifen in decreasing the risk of invasive breast cancer, but was less effective in decreasing the risk of DCIS. However, with longer follow-up, raloxifene was inferior to tamoxifen in the prevention of invasive breast cancer (RR, 1.24; CI, 1.05–1.47), and the difference in rates of DCIS was no longer statistically significant (RR, 1.22; CI, 0.95–1.59) (280). Raloxifene was associated with a reduced incidence of endometrial cancer (RR, 0.55; CI, 0.36–0.83) and thromboembolic event (RR, 0.75; CI, 0.6–0.93) compared to tamoxifen. Overall, there was no difference in mortality.

More recently, the MAP.3 trial evaluated exemestane for prevention in postmenopausal women with increased risk of breast cancer. The eligibility criteria were similar to the NSABP-P1 trial except for the menopausal status. A total of 4,560 women were randomized to exemestane or placebo. At 35 months, treatment with exemestane reduced the risk of breast cancer by 65% (281).

Based on these trials, both raloxifene and tamoxifen are FDA approved for cancer prevention. While tamoxifen can be used in both pre- and postmenopausal women, raloxifene is reserved as a risk-reducing agent only in postmenopausal women who would have met risk eligibility for the NSABP P-2 trial. Aromatase inhibitors appear to be very promising preventive agents for postmenopausal women and offer another effective option with a different toxicity profile. Another large study exploring the use of anastrozole as a preventive agent in women with a family history of breast cancer or increased breast density is currently underway.

RADIATION THERAPY

Radiation therapy is an important and well-established treatment modality for women with breast cancer. Radiation therapy has been shown to reduce the risk of local and regional recurrence and to prevent the need for salvage mastectomy in women undergoing BCS as well as to improved local and regional control in women following mastectomy who have high-risk disease. Importantly, this reduction in local failure has been shown to translate into improved OS with long-term follow-up (282).

Breast-Conserving Therapy

Breast-conserving therapy (BCT) consisting of adjuvant radiation following BCS is the standard approach selected by the majority of women with localized, operable breast cancer. This approach has been validated through multiple randomized phase III trials (80–82,84,283–288). Relative contraindications for BCT include disease not amenable to local excision with

acceptable cosmesis, multicentric disease, persistent positive surgical margins, active pregnancy, connective tissue disorder (especially scleroderma and lupus), and prior breast irradiation.

Although one of the earliest trials evaluating BCT showed inferior results compared with mastectomy, this trial used insufficient radiation doses by modern standards. Subsequent trials conducted in both Europe and North America have all shown equivalent DFS and OS between BCT and mastectomy. The results of these trials are summarized in Table 28.7. The largest of these was NSABP B-06. This trial randomized 1,843 patients to one of 3 arms: total mastectomy, lumpectomy alone, or lumpectomy with radiation. Twenty-year follow-up results are now available. Fisher et al. reported a DFS rate of 36% and 35% ($p = 0.26$) and an OS rate of 47% and 46% ($p = 0.57$) for total mastectomy and lumpectomy with radiation, respectively (131). Local disease control was also similar: 90% and 86%, respectively.

The importance of radiation therapy as part of BCT has also been meticulously evaluated in multiple studies (Table 28.8). These studies show a consistent high rate of local failure with BCS alone, and a two-thirds reduction in failure with the addition of radiation therapy (131,285–287). NSABP B-06 again is the largest of the studies addressing this question, randomizing 1,262 patients to lumpectomy versus lumpectomy and radiation. Twenty-year follow-up results show local failure of 39% with lumpectomy alone and 14% with lumpectomy and radiation (131).

None of these trials individually have shown a difference in OS, although this is not unexpected since these studies were generally not powered to assess this endpoint. To address this shortcoming, the EBCTCG performed a meta-analysis of individual patient data from these randomized trials (289). This included 10,801 patients from 17 randomized trials of BCS with and without radiation therapy. The results show that the risk of first recurrence (local or distant) at 10 years was reduced from 35% to 19% with the addition of radiation therapy ($p < 0.0001$). More importantly, this reduction in recurrence translated into an OS benefit seen at 15 years follow-up with an absolute reduction in overall mortality of 3.8% ($p = 0.0005$). This absolute reduction in all-cause mortality was even higher in high-risk patients; 7.8% high-risk node-negative and 8.5% for node-positive patients. In general terms, for every 4 recurrences prevented with adjuvant radiation therapy, one death is prevented. The monumental undertaking of this meta-analysis of individual patient data is

very important as it demonstrates that with adequate statistical power, local disease control does in fact impact OS. Furthermore, long-term follow-up is necessary as the survival benefit was not seen until beyond 10 years. This improvement in survival is similar to what is achieved with systemic chemotherapy (215).

Despite these benefits for adjuvant radiation therapy, the question of whether some patients undergoing BCS may not require irradiation has been investigated. In 1989, the NSABP initiated the B-21 trial evaluating women with low-risk disease undergoing BCS. Women of all age with tumors less than or equal to 1 cm, ER+ and lymph node-negative were included. Patients were randomized to adjuvant treatment with tamoxifen alone versus radiation alone versus both radiation and tamoxifen with primary endpoints of in-breast tumor recurrence (IBTR) and incidence of contralateral breast cancer. This study enrolled over 1,000 women, and showed that tamoxifen was not as effective in preventing IBTR as radiation when given as a single therapy and that both were less effective than the combination of radiation and tamoxifen. The incidence of IBTR at 8 years was 16.5%, 9.3%, and 2.8%, respectively. Another sub-group felt to be at lower risk of recurrence is older patients as they tend to have more indolent tumor biology. A trial by the CALGB evaluated the additional benefit of radiotherapy in women 70 years of age or older treated by lumpectomy and tamoxifen. These women had tumors less than 2 cm in size, and were ER+ and lymph node-negative. While the rate of local recurrence was again higher among women who did not receive radiation at 5 years (4% vs. 1% in those who received breast radiation, $p < 0.001$), the absolute benefit of radiation was small, making tamoxifen alone a valid option in this patient population.

In summary, BCS with adjuvant radiation results in similar outcomes to mastectomy and is an appropriate treatment option for most patients with early-stage breast cancer. Adjuvant radiation reduces the risk of in-breast recurrence following BCS even in patients with early, low-risk disease, and should be administered as standard therapy following BCS in all patients. One notable exception is for women over the age of 70 who meet the CALGB trial criteria. These patients can be offered tamoxifen alone.

Postmastectomy Radiation Therapy

For women who undergo mastectomy and are deemed to be at moderate to high risk for local failure, radiation therapy to the chest wall and regional lymphatics is indicated. The criteria that defines “moderate” and “high” risk has evolved over time and continues to evolve as our understanding of the important factors related to local-regional recurrence grows. Early trials of postmastectomy radiation therapy showed a decrease in local recurrence but no benefit in OS (131,282,290). These trials varied greatly in radiation technique and dose, and did not include systemic therapy. Three modern-era trials have evaluated the benefit of postmastectomy radiation therapy. The Danish Breast Cancer Cooperative group (DBCCG) conducted 2 randomized trials. The first involved 1,708 premenopausal women with pathological stage II or III breast cancer who were randomized to CMF chemotherapy with or without irradiation of the chest wall and regional nodes. Radiation therapy was associated with a reduction in locoregional recurrence (alone or with evidence of distant disease) over those who received chemotherapy only, 9% versus 32%, respectively ($p < 0.001$). It was also associated with a survival benefit at 10 years where 54% who received radiation were alive, compared to 45% who had received CMF only ($p < 0.001$). The second DBCCG trial randomized postmenopausal women with stage II–III breast cancer to tamoxifen (30 mg/day for 1 year) with or without radiation therapy (292). Over 1,300 women were enrolled, and with a median follow-up of over 10 years, radiation therapy was associated with a significant reduction in locoregional

Unless otherwise stated, trastuzumab treatment was for a total duration of 1 year.

^aJoint analysis of 3,351 women (1,679 receiving AC → T; 1,672 receiving trastuzumab) reported survival analysis at 4 years.

^bThe second interim analysis reported survival endpoints at 4 years.

^c1,010 women were randomized in the FinHER trial to vinorelbine vs. docetaxel, followed by FEC. The subgroup with HER2/neu+ disease underwent additional randomization to trastuzumab or no trastuzumab

recurrence, 8% versus 35% with tamoxifen alone ($p < 0.001$). OS was also improved: 45% and 36%, respectively ($p = 0.03$). Over half of the women enrolled in this trial had only 1 to 3 positive axillary lymph nodes, and the benefit of postmastectomy irradiation was similar in these patients as to those who had 4 or more lymph nodes involved. The DBCCG trials have been criticized for the low number of axillary lymph nodes removed on axillary dissection and the higher than expected axillary failure rates in the control groups. Another trial conducted in British Columbia also addressed the question of postmastectomy irradiation by randomizing over 300 women to CMF chemotherapy with or without radiation therapy. This trial also showed a locoregional control benefit and OS benefit to radiation therapy, yet unlike the Danish trials, the median number of axillary lymph nodes removed on axillary dissection was 11. At 20-year follow-up, isolated recurrence was 10% versus 26% and OS was 47% versus 37% in favor of postmastectomy irradiation (291). The relative magnitude of benefit from radiation therapy was similar in women with 1 to 3 positive nodes (HR, 0.76; 95% CI, 0.50–1.15) compared to those with ≥ 4 positive nodes (HR, 0.70; 95% CI, 0.46–1.06) (292). The EBCTCG also performed a meta-analysis of individual patient data from randomized trials of postmastectomy radiation therapy (282). This analysis included 8,500 women, and for those with any involved axillary nodes, a statistically significant 17% absolute reduction in 5-year local recurrence (6% vs. 23%) and a 4.4% absolute improvement in 15-year OS (40.2% vs. 35.8%) was shown.

Postmastectomy radiation therapy, therefore, should be administered to all patients with locally advanced disease (T4 or ≥ 4 positive nodes). Radiation therapy should also be offered to patients with one to 3 positive nodes or involved surgical margins as these patients are also at moderate to high risk for local recurrence (293). Furthermore, a subset of patients with node-negative disease is at risk for recurrence and may benefit from postmastectomy radiation therapy. A combination of some of the following risk factors defines this later group: young age, T2

or greater disease, lymphovascular space invasion, close margins, and triple negative disease (ER, PR, and HER2/neu negative) (294–296).

Radiation Therapy for *In Situ* Breast Disease

Approximately 20% to 30% of patients treated with local excision alone for DCIS have a recurrence, with about half of these recurrences being invasive cancer. Given this, radiation is often delivered as a means of risk reduction. To date, 4 randomized trials have compared excision alone with excision followed by whole breast radiation therapy, and all have demonstrated that radiation therapy reduces the risk of a subsequent breast event by 38% to 62% (297).

The NSABP B-17 trial enrolled over 800 women with localized DCIS and randomized them to lumpectomy with or without radiation therapy. A statistically significant reduction was seen in both noninvasive IBTR (13.4% without radiation vs. 8.2% with radiation, $p = 0.007$) and invasive IBTR (13.4% vs. 3.9%, respectively, $p < 0.0001$) (293). EORTC 10853 enrolled over 1,000 women with surgically excised DCIS up to 5 cm in widest diameter and randomized them to observation or radiation therapy. The reported 4-year local relapse rate was 84% and 91%, respectively ($p = 0.005$), with similar reductions seen in both invasive and noninvasive recurrences. The SweDCIS trial enrolled over 1,000 women and showed a 60% relative reduction of IBTR with radiation corresponding to an absolute reduction in recurrence of 16% at 10 years (297). Lastly, Houghton et al. reported on a 2×2 randomized trial (UKANZ) in this population where over 1,700 women were randomized to both radiation and tamoxifen, either as a single agent, or to no further therapy. With a median follow-up of 53 months, radiation therapy reduced IBTR (HR, 0.68; 95% CI, 0.49–0.96). The reduction in IBTR was seen for both invasive disease (HR, 0.45; 95% CI, 0.24–0.85) and noninvasive disease (HR, 0.36; 95%

CI, 0.19–0.66). Interestingly, this is the only randomized trial to assess tamoxifen alone in the absence of radiation therapy for preventing local recurrence, and no benefit was seen. The impact of tamoxifen combined with radiation therapy was the focus of NSABP B-24. This trial showed that the addition of tamoxifen further reduced the number of invasive breast cancer events by 50%. Tamoxifen also reduced the risk of invasive disease in the contralateral breast, but had a nonsignificant effect on reducing DCIS recurrences in either breast. Finally, a recent meta-analysis of the aforementioned trials evaluated the role of radiation following breast-conservation surgery for DCIS. This analysis demonstrated a 54% reduction in local recurrence (298). The same proportional benefit was seen across all risk groups with the largest absolute benefits seen in patients with high-risk factors; size >2 cm, high grade, presence of comedonecrosis, and positive resection margins. However, even in women with small, low-grade tumors resected with negative margins, the absolute reduction in IBTR with radiation therapy at 10 years was still 18%. No significant difference in breast cancer-specific mortality or overall mortality was seen.

Attempts at identifying subgroups of patients at low risk for recurrence following excision alone have met with limited success. Wong et al. prospectively evaluated a series of patients treated with wide resection margins of at least 1.0 cm and still reported a 5-year recurrence rate of 12% (91). A prospective trial ran by ECOG evaluated patients with low-grade tumors less than 2.5 cm and high-grade tumors less than 1.0 cm. Five-year IBTR was 6.1% in the low-grade group and 15.3% in the high-grade group despite a mean tumor size of only 6 mm and 5 mm, respectively (299). Several stratification systems have been proposed (33,37,300) evaluating various clinical and pathologic factors in an attempt to identify subgroups at low risk of recurrence. Unfortunately, none have been substantiated by external validation (301–303). It appears that although many of the clinical and pathologic factors related to risk of recurrence are known, some patients with seemingly low-risk DCIS develop recurrence. It is clear that our understanding of the underlying biology of DCIS based on these factors is incomplete. Novel molecular or genetic markers may prove useful in this regard.

In summary, adjuvant radiation therapy following local excision of DCIS reduces the risk of local recurrence by approximately 50%, and tamoxifen provides an additional benefit in reducing the risk of invasive recurrence. This approach, however, has not been shown to improve DFS or OS. As such, radiation therapy as a risk reduction strategy for local recurrence should be discussed with each patient. The decision whether to proceed with treatment needs to involve the active participation of the patient, and should take into account the individual's clinical and pathologic risk factors to help assess the overall risk of recurrence, and thus the expected absolute benefit of radiation therapy, as well as the potential side effects and toxicities of therapy.

Partial Breast Irradiation

Standard radiation therapy consists of irradiating the whole breast; however, for select patients, partial breast irradiation is an option. The concept of partial breast irradiation arose out of the realization that the majority of tumor recurrences occur at or near the region of the lumpectomy site, and is supported by pathologic correlation (286,304,305). Thus, for well-selected patients, only the breast tissue surrounding the tumor bed needs radiation treatment. Limiting radiation therapy to a smaller portion of the breast results in 2 major advantages. First, there is reduction in volume of irradiated tissue thereby preserving these tissues for potential deleterious radiation effects. This includes minimal to no dose exposure to the heart and lung. Second, by reducing the volume of treatment, the overall treatment time

can be safely accelerated to deliver the entire course of radiation within a week or less. This approach is referred to as accelerated partial breast irradiation (APBI), and is generally defined as radiotherapy delivered to less than the whole breast employing fractions higher than 1.8 to 2.0 Gy per day over a period of less than 5 to 6 weeks. Multiple techniques have been developed and are being developed for the delivery of APBI. In North America, the most commonly used techniques are multicatheter interstitial brachytherapy, intracavitary brachytherapy, and 3-D conformal external beam radiation therapy. Multiple single-institutional as well as multi-institutional trials, some with follow-up beyond 10 years, have demonstrated results comparable to whole breast irradiation (306). A matched-pair analysis was performed at the William Beaumont Hospital where 199 patients who received APBI via an interstitial approach were compared to 199 patients treated with whole breast irradiation at the same institution. Shah et al. recently reported 12-year follow-up results showing no difference between the 2 groups in local control, regional control, cause-specific survival, or OS (307). The local failure was 5.0% and the cause-specific survival was 95% in both groups. To establish level I evidence for the equivalency of APBI and whole breast radiation therapy, the NSABP/Radiation Therapy Oncology Group and the Groupe Européen de Curiethérapie and the European Society for Radiotherapy and Oncology collaborative groups are conducting phase III randomized trials. Until these trials mature, the American Brachytherapy Society (ABS), American Society of Breast Surgeons (ASBS), and American Society of Therapeutic Radiation Oncology (ASTRO) have published guidelines for appropriate patient selection for APBI (Table 28.9) (308).

Radiation Therapy for Recurrent Disease

Recurrent disease involving the chest wall or regional lymphatics is often a marker of aggressive disease biology, and up to 80% of patients will develop subsequent distant metastatic disease (309). Aggressive local therapy with surgery and/or radiation is, however, warranted as cure can be achieved in some of these patients; furthermore, the prevention of the significant morbidity of uncontrolled, local disease is of benefit.

Table 28.9 Selection Criteria for Accelerated Partial Breast Irradiation

Criteria	ABS	ASBS
Age	≥45 years	≥45 years
Histology	IDC	IDC or DCIS
Size	≤ 3 cm	≤ 3 cm
Margin	Negative	Negative microscopic margin
Axillary Node Status	Negative	Negative

Note: ABS, American Brachytherapy Society; ASBS, American Society of Breast Surgeons; DCIS, ductal carcinoma *in situ*; IDC, invasive ductal carcinoma.

Radiation Therapy for Metastatic Disease

Oligometastatic disease is a condition that has been recently recognized in many solid tumors. Oligometastasis is defined as a transitional state between localized disease and widespread systemic disease, where the volume and number of metastatic deposits is limited, and local and/or systemic therapy may result in cure (310). Although only a small percentage of these patients can have long-term DFS, this is in distinct contrast to patients with widespread metastatic disease where cure is not possible. While such tumor biology is considered quite rare in breast cancer, aggressive local therapy with radiation and/or surgery should be considered for select patients. Stereotactic body radiation therapy (SBRT) or stereotactic radiosurgery (SRS) is an ideal method for radiation therapy for these patients. With this method, high ablative doses of radiation are delivered in a highly conformal manner with extreme precision. This is typically done in just 1 to 5 treatments or fractions and can be applied not just to the brain but almost any part of the body. The large radiation doses result in a high probability of local disease control, and the conformality and precision allow for a low risk of side effects and complications (311,312).

For patients with widespread metastatic disease, radiation therapy can be used effectively for palliation of lesions involving the chest wall, regional lymphatics, bone, brain, lung, and liver, among other areas. Indications for radiation in this setting include palliation of symptomatic lesions not responding or unlikely to respond to systemic therapy, and prevention of complications of local disease progression, such as impending pathologic fracture from bone metastasis, impingement of the spinal cord or nerve roots from spine metastasis, or neurologic sequelae from brain metastases. Palliative radiation courses usually last from a one-time, 8-Gy one-day treatment to a 2-to-3 week course of 2.5 to 3 Gy per fraction for a total dose of 30-37.5 Gy (313). Some well-localized lesions can also be treated with SBRT.

Radiation Therapy Techniques

Radiation treatment planning and delivery has dramatically evolved since the inception of BCT; from low-energy Cobalt units using indiscriminant en face treatment fields, to high-energy linear accelerators with rudimentary 2-D planning, and now to modern CT-based, 3-D treatment planning with sophisticated dose modulation. This is important to understand as we have come a long way in our ability to spare normal tissues, and this needs to be considered when evaluating long-term toxicity data from techniques that are clearly far inferior and posed substantial risk to underlying organs as compared to modern methods.

For modern radiation treatment planning, the process begins with the “simulation.” This is a session at which the patient position for treatment is established. For breast cancer, this is typically in the supine position with the ipsilateral arm up, although other treatment positions are sometimes used to optimize target and normal tissue geometry. Appropriate immobilization devices are used to ensure stability and reproducibility of the patient position during daily treatments. Tattoos are placed to allow for precise positioning with aid of in-room targeting lasers. A CT scan is obtained in the established treatment position. This data set is used to design treatment portals and to perform dose calculations. This allows for tailoring the treatment fields to the specific anatomy of the patient and allows for optimization of target doses and normal tissue sparing. Once an appropriate treatment plan is generated, the virtual plan is verified on the patient via imaging through the treatment portals.

The whole process undergoes rigorous quality assurance procedures to ensure the upmost accuracy in all facets of treatment delivery (314-317).

Intact Breast

Following BCS, the entire residual breast tissue is included in the irradiated volume with or without regional lymph node groups depending on the risk of subclinical disease spread to these regions. Treatment portals are oriented tangential to the breast to avoid lung and heart irradiation. Photon energies of 4 to 6 MV are preferred to treat the breast. Energies greater than 6 MV may underdose superficial tissue beneath the skin surface, but may be helpful in decreasing hot spots for patients with large breasts. Dose modulation with wedges, tissue compensators, electronic compensation (field-in-field techniques), or intensity modulated radiation therapy (IMRT) is used to optimize dose distribution and dose homogeneity across the target volumes. The prescription dose used is 45 to 50.4 Gy in 1.8 to 2.0 Gy per fraction over 25 to 28 treatments given 5 days per week over 5 to 6 weeks. This is followed by a boost to the tumor bed consisting of 10 to 16 Gy in 1.8 to 2.0 Gy per fraction to a total dose of 60 to 66 Gy over 6 to 7 weeks of treatment.

The tumor bed has the highest risk of harboring subclinical or microscopic disease, and clinical evidence has shown that it is the site at highest risk for recurrence. The value of adding a tumor bed boost was evaluated by 2 randomized trials. The EORTC 22881-10882 trial involved over 5,300 women with stage I or II breast cancer who were randomly assigned to whole breast treatment with or without a tumor bed boost of 16 Gy. At 10 years, the rate of local relapse was significantly lower in the boost arm: 10.2% versus 6.2% ($p < 0.0001$). There was no difference in OS: 82% in both arms. A subsequent randomized trial from Lyon, France also showed a reduction in local relapse with a 10 Gy boost. The boost targets the lumpectomy cavity with an appropriate margin and can be delivered using one of several techniques, including en face electrons, 3-dimensional conformal radiation therapy (3D-CRT), IMRT, Accuboot or other brachytherapy techniques.

Recent data have emerged that for select patients, hypofractionated whole breast radiation is an appropriate option. This allows for shorting the overall treatment time to about 4 weeks from 6 to 7 weeks with standard fractionation. Whelan et al. reported an update of the Canadian study which randomized over 1,200 women to either standard whole breast irradiation (50 Gy in 25 fractions) or to a hypofractionated regime (42.5 Gy in 16 fractions). The local control at 10 years was similar; 6.7% for standard fractionation and 6.2% for hypofractionation. Good to excellent cosmetic outcome was also similar; 71.3% and 69.8%, respectively. Further studies from the United Kingdom have substantiated these findings (317).

Chest Wall

For women at high risk for local or regional recurrence following mastectomy, radiation therapy is delivered to the chest wall and regional lymphatics. Similar to intact breast treatment, a 3D-CRT technique using tangentially oriented beams is used. Tissue-equivalent bolus material is used on the chest wall surface, for at least a portion of the treatment, to increase dose build-up in superficial chest wall tissues. Other techniques, such as en face electrons fields, mixed electron and photon fields, and IMRT can also be used to target the tissues at risk. The typical prescription dose is 45 to 50.4 Gy in 1.8 to 2.0 Gy per fraction over 25 to 28 treatments over 5 to 6 weeks. This can be followed by a boost to the mastectomy scar/operative bed to a total dose of 60 to 66 Gy.

For patients undergoing mastectomy, reconstructive options are an important consideration for most women. The plastic surgeon should be involved early in the multidisciplinary management of these patients as many factors can have significant implications on the ultimate cosmetic outcome. Among these factors are the type of reconstruction used, and sequencing of reconstruction and postmastectomy radiation.

Regional Lymphatics

From a radiation oncology perspective, the regional lymphatics are divided into 4 anatomical groups: low axilla (level I and lower level II), high axilla (high level II and level III), supraclavicular fossa (SCF), and internal mammary chain (IM). Each of these regions can be targeted based on risk of subclinical disease involvement. The low axilla is inadvertently included in most tangential whole breast radiation fields. This typically includes the first echelon lymph nodes as most sentinel nodes are found in these regions (318). For patients who are node-negative, the risk of failure in the axilla or SCF is uncommon, and inclusion of these nodal regions is not necessary. For patients with involved axillary lymph nodes, and particularly those with 4 or more involved nodes, the SCF is at risk and should be treated (319). The SCF is typically treated with a single anterior oblique field that is matched to the tangential breast fields. The matching technique is crucial to prevent beam overlap and thus significant dose hot spots at the beam junctions. For patients with involved axillary lymph nodes who undergo a completion axillary dissection, treatment of the high axilla is generally not necessary as the risk of failure after an *en bloc* resection is not common (319). Avoiding irradiation of the high axilla in these patients is desirable as irradiation increases the risk of arm lymphedema following axillary dissection (320). Thus treatment of the high axilla is typically reserved for patients at high risk of subsequent axillary failure. This includes patients who do not undergo axillary evaluation but are at risk for axillary lymph node involvement, patients with positive sentinel lymph nodes who do not undergo a completion dissection, and patients with involved axillary lymph nodes who undergo dissection but have high-risk factors. The high axilla is typically treated by extending the oblique SCF field laterally. Often a posterior field, posterior axillary boost, or PAB, is added to supplement dose to the posterior portion of the axilla.

The treatment of the IM nodes is controversial. Classic surgical data have shown that the risk of IM node involvement can be as high as 20%, particularly for patients who have medial tumors and involved axillary lymph nodes (321,322). However, clinical failure in the IM chain, even in these patients, is uncommon, less than 1% (323). A randomized trial evaluating the treatment of IM nodes is currently underway and will help answer this unresolved question. The IM nodes are located in the first 3 intercostal spaces adjacent to the internal mammary vessels, just lateral to the sternum. Several techniques can be used to target the IM nodes. The most common methods are either a matched en face or oblique electron field, or a modification of the whole breast tangential beams. Regional lymph nodes are treated to a total dose of 45 to 50.4 Gy in 1.8 to 2.0 Gy per fraction.

The importance of regional lymph node irradiation was the focus of the Canadian Clinical Trials Groups protocol MA.20. This study included over 900 patients with 1 to 3 involved lymph nodes undergoing BCS and were randomized to whole breast radiation therapy with or without regional nodal irradiation. Early results have been reported and they show a statistically significant improvement in DFS, isolated local-regional DFS, distant DFS, and a trend to improved OS.

Accelerated Partial Breast Irradiation

Numerous techniques for the delivery of APBI have been employed involving both external beam and brachytherapy techniques. The most common techniques used in North America are interstitial multicatheter brachytherapy (IMB), intra-cavitary balloon brachytherapy (IBB), and 3D-CRT. IMB is characterized by the percutaneous placement of multiple catheters into and surrounding the lumpectomy cavity in such a fashion as to deliver the prescription dose to the tumor bed with a margin of 1.0 to 1.5 cm. This technique is very versatile and can conform to the most complex tumor bed geometry. IBB was developed as a simplification of the IMB technique. IBB involves the percutaneous placement of a single catheter applicator into the lumpectomy cavity. This is performed either at the time of surgery under direct visualization with an open cavity, or postoperatively under US and/or CT guidance. Once the end of the applicator is positioned within the lumpectomy cavity, the balloon at the end of the applicator is inflated to conform to the cavity. Dose is prescribed to a 1.0 cm distance from the balloon surface to encompass the tumor bed with an appropriate margin. Several balloon and balloon-like catheters are commercially available including Mammosite, Contura, and SAVI. APBI using 3D-CRT is an external beam technique, which employs 4 to 5 noncoplanar, tangential-oriented beams targeted to the lumpectomy cavity. To account for breast motion, respiratory motion, patient motion, and set-up error, a larger margin of 2.5 cm is used with this technique. A prescription dose of 34.0 Gy in 10 fractions given twice daily is used for IMB and IBB and a dose of 38.5 Gy in 10 fractions is used for APBI using 3D-CRT.

Future Directions in Radiation Therapy

APBI is now an established approach to treating well-selected patients. However, several aspects of APBI remain areas of active research. Which patients are appropriate for this approach still remains to be determined. Patients defined as “appropriate” by the ASTRO criteria are clearly good candidates for this approach, but emerging data show that at least some patients in the “cautionary” and even in the “unsuitable” categories may be appropriate for APBI as well (324,325). We have learned and continue to learn about the limitations of the established techniques as long-term toxicity data emerge (326–328). Novel approaches to deliver APBI are being developed and investigated to overcome some of the limitations and shortcomings of the existing techniques. Novel approaches include electronic balloon catheter brachytherapy (Xoft), permanent breast seed implantation (PBSI), Gamma Pod, CyberKnife, prone position external beam techniques, mixed photon and electron external beam techniques, proton beam, intra-operative electrons or photons, and noninvasive image-guided breast brachytherapy (AccuBoost). It is likely that no one technique will prove superior in all scenarios, but which collection of techniques will prove to be most optimal is yet to be determined.

Another important area for future investigation is to continue to better define subgroups of patients who benefit from and those that may forgo radiation therapy. A recent analysis showed that women with triple-negative disease undergoing mastectomy had a higher rate of local-regional failure compared to women undergoing BCS and radiation therapy (329). This suggests that there are populations of patients who undergo mastectomy but are not offered radiation therapy because they are felt to be at low risk and yet ultimately develop recurrence. Further data to clearly define these at-risk groups are needed. Conversely, data need to define whether or not all patients undergoing BCS need radiation. The CALGB trial

evaluating women over the age of 70 defined one such group which can be treated without radiation therapy. Are there other low-risk groups? The answer likely is yes. But appropriately defining these groups remains a challenge. Nomograms can be useful for this purpose and are being developed (330,331). One such nomogram, IBRT!, was developed using known clinical and pathologic variables, and has undergone external validation (331). Tumor-specific genetic signatures may also prove to be helpful as they have been for determination of benefit from chemotherapy (332).

Pregnancy-Associated Breast Cancer

Breast cancer is one of the most frequently diagnosed cancers during pregnancy. Pregnancy-associated breast cancer (PABC) is defined as cancer diagnosed either during pregnancy or up to 12 months postpartum. The incidence of PABC ranges from 0.02% to 0.1% (333). As increasing numbers of women delay pregnancy, many speculate that the incidence of PABC will increase. Deciding on the best treatment of PABC is challenging due to potential conflicts between maternal and fetal well-being.

While breast examination is limited in a pregnant patient due to hormonally-induced breast engorgement, most women diagnosed with PABC present with a painless breast mass, and while the majority of palpable masses identified during pregnancy are benign, including lactating adenomas, fibroadenomas, and galactoceles, evaluation is warranted if palpable findings persist. Unfortunately, given the physiological changes associated with pregnancy, diagnostic delays are common and are believed to contribute to the advanced stages at diagnosis among pregnant women. Typically, breast US is the first diagnostic approach used to evaluate a palpable breast and/or axillary mass during pregnancy given its safety and high sensitivity and specificity (334). Following a diagnosis of breast cancer, mammography may be helpful to diagnose multicentric, multifocal and/or bilateral breast cancer. MRI has been used during pregnancy; however, as gadolinium crosses the placenta and has been associated with fetal abnormalities in rats (Category C), contrast-enhanced breast MRI is not recommended (335).

Although the usefulness of mammography during pregnancy has been questioned, recent studies have reported on both the safety and relative efficacy of mammography during pregnancy. With proper abdominal shielding, the irradiation dose to the fetus from a standard 2-view mammogram is less than 50 mrad (0.5 μ Gy). It is within the limits considered acceptable during pregnancy and well below the threshold exposure of 10 rad (100 mGy), where the estimated risk of fetal malformations and CNS problems is 1% (336).

Studies assessing the effectiveness of mammographic and ultrasonographic imaging in PABC are limited. Yang et al. performed a retrospective study of 23 women with 24 cancers diagnosed during pregnancy (337). Of those who underwent preoperative mammography, radiographic findings were “positive” in 18/20 cancers (90%) despite dense breast parenchymal patterns. The addition of ultrasonography was noted to be 100% sensitive in the work-up of the palpable mass during pregnancy. Ultrasound-guided core biopsies can be performed safely and are the preferred method for diagnosis. A percutaneous biopsy of any lesion that does not meet the criteria for a simple cyst has been recommended (338). Despite concerns to the contrary, reports of milk fistulae are rare. Furthermore, gestational changes of the breast may lead to false-positive and/or false-negative results with fine-needle aspirate cytology and should be interpreted with caution. The use of other imaging modalities should be limited to those required for treatment planning. Metastatic evaluations acceptable during pregnancy

include chest radiographs, abdominal/liver ultrasonography, and noncontrast skeletal MRI (339).

Historically, studies reported that PABC had a dismal prognosis, with survival rates of less than 20% at 5 years (340,341). These statistics likely reflect a more advanced stage of diagnosis, as PABCs are typically larger and more often node-positive (56% to 89%) compared to nonpregnant women (38% to 54%) (342). Most pregnant patients are diagnosed with infiltrating ductal adenocarcinomas associated with aggressive histologic phenotype and these are often high-grade, HR-, and *HER2/neu+* with associated LVI (343). After controlling for patient age and stage of diagnosis at presentation, the overall prognosis of patients appears similar to that of nonpregnant women, and the 5- and 10-year survival for node-negative and node-positive PABC ranges from 60% to 100%, and 31% to 52%, respectively (344,345). Despite this, controversy still persists, and a recent retrospective study demonstrated a higher risk of recurrence and death among women with PABC compared to nonpregnant controls (346).

Treatment

Treatment strategies are determined by tumor biology, stage, gestational age, and patient/family wishes. Treatment guidelines for pregnant women essentially follow those set forth for nonpregnant women with the exception of radiotherapy. There is no role for pregnancy termination with the goal of improving prognosis. A multidisciplinary approach is essential to providing optimal care, allowing for cooperation between medical, surgical, and radiation oncology, radiology, obstetrics, and neonatology.

Surgery

The safety of surgical intervention at any stage in the pregnancy is well established, and a modified radical mastectomy has traditionally been considered the standard of care. This approach virtually eliminates the need for irradiation and allows optimal control of disease within the axilla. However, given that most women with PABC will receive adjuvant or NACT, resulting in a delay of radiotherapy after delivery, BCS is increasingly seen as a reasonable alternative to pregnant women, particularly if the diagnosis is made in the latter second and third trimesters.

Lymph node staging remains the most important predictor of systemic recurrence, and accurate nodal staging is crucial to determining appropriate systemic therapy. As in nonpregnant patients, axillary ultrasonography and image-guided FNA of suspicious nodes may be helpful in diagnosing those patients with locally advanced disease. This is of particular relevance to patients for whom neoadjuvant therapy is being considered. Although the sensitivity and specificity of sentinel lymph node (SLN) biopsy in pregnancy have not been systematically evaluated, this technique has been used successfully in pregnant patients, and SLN staging with the use of Tc-99 colloid is considered safe in pregnancy (347,348). The lower radioactive dose associated with the 1 day protocol is preferred. Of note, however, both isosulfan blue dye and methylene blue dye are classified as pregnancy category C drugs. Intra-amniotic injection of methylene blue has been associated with hemolytic anemia, hyperbilirubinemia, methemoglobinemia, duodenal atresia, deep blue staining of the newborn, and even fetal death, and is best avoided (349).

Radiotherapy

Most experts consider postoperative therapeutic irradiation during pregnancy to be contraindicated. If breast conservation is chosen, adjuvant radiotherapy is typically delayed until the postpartum period. This perspective has been challenged by

some who feel that the risks of radiation to the fetus are overestimated and exposure can be reduced sufficiently by proper shielding, resulting in fetal exposure doses which fall below accepted threshold levels (350). Kouvaris et al. reported the case of a 45-year-old woman treated with radiation during the first trimester of pregnancy who delivered a healthy male neonate at 39 weeks of gestation. The lack of prospective data and the option of mastectomy for patients with PABC, however, continue to make the use of radiotherapy during PABC contraindicated.

Systemic Therapy

Given the high prevalence of node-positive disease with adverse pathologic features among women diagnosed with PABC, chemotherapy plays a crucial role in both the adjuvant and neoadjuvant treatment of these women. The effects of chemotherapy on fetal development and growth vary depending on gestational age at the time of exposure. When administered during the first trimester, chemotherapy effects are characterized as “all-or-nothing” and may result in high rates of miscarriages and congenital malformations (351). As a result, chemotherapy is generally avoided during the first trimester. The second and third trimesters of pregnancy are characterized primarily by fetal growth and maturation, as organogenesis is complete. Outside of the first trimester, chemotherapy has proven to be surprisingly safe, although all chemotherapy agents are considered category D agents. The overall incidence of major fetal malformations is reported to be ~3%, which is similar to the estimated baseline population risk for major congenital malformations (352). Studies have reported growth restriction, intrauterine and neonatal death, prematurity, and haemopoietic suppression. In a recent publication, Cardonick and colleagues reported on the experience of 104 women diagnosed with PABC who received chemotherapy during pregnancy (353). The mean gestational age at diagnosis was 13.2 weeks. All but one patient received anthracycline-based treatment, and 11 patients received additional taxane therapy. None received trastuzumab. The mean gestational age at delivery was ~36 weeks. One neonatal death was reported due to a systemic autoimmune disorder. Four (3.8%) newborns exhibited birth defects. This study showed no increased rate of growth restriction at birth or congenital anomalies compared with population controls.

Several prospective case-series have reported on the use of anthracycline-based chemotherapy administered every 3 to 4 weeks during the second and third trimesters (354). In a prospectively recorded series, Hahn and colleagues reported that among 57 women treated with FAC in the second and third trimesters, there were no stillbirths, miscarriages, or perinatal deaths (355). The median gestational age at delivery was 37 weeks (range, 29 to 42 weeks). The most common neonatal complication was respiratory distress, and 10% required ventilatory support.

Other studies have been reported recently which document the relative safety of chemotherapy for treatment of PABC. The European Institute of Oncology in Milan reported a retrospective series of 20 women with locally advanced or metastatic breast cancer treated with weekly epirubicin after the second trimester (356). The regimen was well tolerated, and the development of children was normal at a median follow-up of 2 years. Azim and colleagues reported the results of anthracycline-based treatment regimens in 26 patients with PABC (357). Chemotherapy was delivered as both adjuvant and neoadjuvant treatment during the second trimester. No growth restriction or pre-eclampsia was reported. All children met normal developmental milestones at 27 months of age.

Many of the patients who present with PABC exhibit characteristics (e.g., young age and adverse prognostic features) that in other circumstances would be treated using a combined

anthracycline- and taxane-based regimen. Historically, however, the taxanes were felt to be contraindicated due to evidence of toxicity in animal studies during organogenesis. More recently, several case reports describe the use of paclitaxel and docetaxel in the second and third trimesters (358,359). A review by Mir et al. identified 40 reports of taxanes used to treat breast, ovarian, and lung cancer in pregnant women (360). There were no spontaneous abortions or intrauterine deaths reported.

Other Therapies

Given the relative frequency of *HER2/neu* over-expressing tumors in women with PABC, treatment with trastuzumab may be considered. There are several case reports on the use of trastuzumab during pregnancy. Watson reported on a case of reversible anhydramnios following treatment with trastuzumab when used at less than 30 weeks gestation (361). Sekar and Stone reported similar results and demonstrated a 7-week delay before anhydramnios was reversed (362). Two other case reports found no fetal or neonatal complications (363,364). Trastuzumab is considered a category B drug in pregnancy, but given these data, it appears prudent to limit its use in pregnancy if possible. When used, serial monitoring of these pregnancies is warranted, particularly with regards to oligo-/anhydramnios.

Given that the majority of PABCs are HR-, the use of endocrine manipulation has been less extensively studied among pregnant women with breast cancer. There are no long-term data available of children following exposure to tamoxifen in utero. This, coupled with data from both animal and clinical studies on the potential teratogenicity of tamoxifen, suggest that tamoxifen use is best reserved until completion of the pregnancy, and the use of nonhormonal contraception is recommended during tamoxifen treatment and for 2 months after stopping, due to its extended half-life (365). Bisphosphonates have also shown promise in the treatment of premenopausal patients in combination with endocrine therapy (366); however, animal studies have shown significant fetal toxicities, including fetal underdevelopment, fetopathy, hypocalcemia, and skeletal retardation. Bisphosphonates are therefore contraindicated in pregnancy.

Developmental Effects

The potential risk of anthracycline-associated fetal cardiotoxicity later in life during childhood or adulthood remains a concern for fetuses exposed to chemotherapy in utero. Meyer-Wittkopf et al. did not identify any abnormalities on echocardiograms performed in utero and up to 2 years of age on infants exposed to doxorubicin and cyclophosphamide starting at 24 weeks gestation (367). Additionally, evaluation of 81 children who received anthracycline treatment in utero detected no abnormalities at a median follow-up of 17 years (368).

Others have voiced unease over the potential long-term developmental sequelae of in utero exposure to chemotherapy. Aviles and Neri reported on a cohort of 84 children born to mothers who received combination chemotherapy during pregnancy for hematological malignancies (369). Physical, neurological, and psychological development were normal for all children, and there were no malignancies diagnosed in this group of children. Finally, a recent study by Amant et al. documented the outcomes of 70 children exposed to chemotherapy during pregnancy. No differences were reported in general health and growth, CNS, cardiac, and auditory function. Prematurity was frequently reported, however, and was associated with cognitive impairment, stressing the importance of avoiding iatrogenic premature delivery whenever possible. At present, the dosing recommendations for chemotherapy during pregnancy are weight-based. Current recommendations are to avoid the administration of chemotherapy approximately one

month prior to delivery in order to minimize the possibility of infectious complications or hemorrhage to both the mother and the fetus from pancytopenia.

Pregnancy After Breast Cancer Treatment

It has been reported that approximately 5% to 15% of young breast cancer survivors will become pregnant. To date, there are no prospective studies evaluating the safety of a subsequent pregnancy after a diagnosis of breast cancer. Several retrospective studies have demonstrated no worsening of survival or increased risk of recurrence, although these studies are subject to significant biases and limitations (370). Of note, a number of studies reported an improved survival in women who became pregnant after breast cancer (371), and the issue of the “healthy mother effect” as a potential confounder has been reported. The reasoning is that only women who feel physically and emotionally healthy will attempt pregnancy, while those who continue to be affected by the disease do not. Alternatively, it is possible that the high hormonal levels of pregnancy have a beneficial effect given the documented anti-tumor effects seen both *in vitro* and *in vivo* animal models of high-dose estrogens and progestins.

For those women who become pregnant following breast cancer treatment, successful breast-feeding following breast conservation and irradiation has been reported. Higgins and Haffty reported on 11 patients who subsequently experienced 13 pregnancies (372). Following delivery, lactation was possible in the treated breast in 4 instances but not in 6 others. In 3 women, lactation was pharmacologically suppressed. In the majority of cases, lactation was possible in the untreated breast. The time interval from initial treatment did not appear to impact successful lactation; however, in 4 instances where lactation was not successful, a circumareolar incision was performed, suggesting that lactation may be less likely to occur in the case of centrally located lesions where the anatomy of central ducts may be altered.

It may seem helpful to wait a period of time prior to attempting pregnancy since this is the time of highest risk of recurrence, but the available data have not clearly shown a worse prognosis if pregnancy is achieved sooner. Furthermore, women with a risk of breast cancer may develop recurrent disease many years after, such that a waiting period of 2 years may not be as reassuring as it seems. In this regard, studies have highlighted patients’ concerns regarding the impact of adjuvant treatment on subsequent fertility options (373,374). Discussing fertility options after receiving treatment for breast cancer may be too late. Thewes et al. found that women prefer to discuss these issues at the time of treatment planning and early follow-up, suggesting that options for preserving fertility should be addressed early, including a referral to a fertility specialist as needed. Recently, ASCO convened an expert panel to develop guidelines for fertility preservation.

Breast Cancer in the Elderly Patient

Age is a well-documented risk factor for the development of breast cancer, and decisions regarding effective therapy can be complicated by a real or perceived limited life expectancy, multiple competing comorbidities, and limited level I evidence. Data from the Surveillance Epidemiology and End Results (SEER) database shows that more than half of all cancers occur in patients aged > 65 years, including approximately 25% aged 75 to 84 years, and almost 10% aged > 85 years. Given the overall increase in life expectancy among women in industrialized countries, higher numbers of otherwise healthy elderly women with breast cancer are anticipated. Unfortunately, large national multi-institutional trials include only a small fraction of these older women. Furthermore, defining the “elderly population” is

problematic. Much of the literature defines “elderly” broadly, and includes women as young as 65 years of age and may even exclude women older than 80 years of age. Despite the high prevalence of breast cancer in older women, there is substantial evidence that they are less likely to receive standard care (375,376) and may have worse outcomes as a result (377,378). Ideally, age alone should not dictate the management of older women with breast cancer. Treatment should be based on a careful, individualized assessment of physiological age, estimated life expectancy, risks, benefits, treatment tolerance, patient preference, and potential treatment barriers (379). While there is currently no standard method of geriatric assessment, tools such as Adjuvant! Online (www.adjuvantonline.com) and the Comprehensive Geriatric Assessment (380) have attempted to estimate the relative benefit of treatment, taking into account both tumor biologic characteristics as well as a patient’s life expectancy.

Compared to younger women, older women are more likely to have breast cancers that are estrogen receptor (ER)- and PR+ and HER2/neu-, and well- or moderately differentiated with a low proliferation index (381,382). Despite these apparently favorable characteristics, some studies indicate that survival from breast cancer appears to be worse among older women. One recent study documented lower 5-year and 10-year relative survival among patients 70 years or older compared to patients aged 40 to 70 years, even when adjusting for disease stage (383). The determinants underlying this finding remain unclear.

Age-related differences in breast cancer survival may be related to differences in disease stage at diagnosis. Tumor size and nodal involvement have been shown to increase with age (381,384), and one analysis of SEER registry data shows older women are diagnosed with metastatic disease more frequently than younger women (385). Conversely, a recent single-institutional study of 1,267 women demonstrated older women had more early-stage cancers and a longer recurrence-free and OS (386). Analysis of 2 large Italian databases has confirmed these data (387).

Surgery

Despite earlier studies suggesting that primary medical treatment with tamoxifen was as effective as surgery for the treatment of operable breast cancer in elderly patients, more recent randomized studies have demonstrated a more favorable outcome following surgical management of these patients (388). A recent Cochrane review also concluded that primary endocrine therapy alone is inferior to surgery for local control of operable breast cancer in older women, and suggests that the option of endocrine therapy alone should be limited to those women whose competing comorbidities preclude them from proceeding to surgery or women who refuse surgery at all (389).

Standard of care for operable breast cancer includes BCS plus whole-breast radiotherapy (WBRT) or mastectomy followed by postmastectomy radiotherapy, as appropriate. Older patients tolerate surgery as well as their younger counterparts, and the operative mortality of patients who are in reasonable health with a reasonable functional status is negligible (390). Careful evaluation of significant comorbidities will identify the small group of women who would suffer significant morbidity and/or mortality from surgery. Furthermore, the widespread adoption and acceptance of axillary sentinel node biopsy has served to decrease further the risk associated with operative management of breast cancer. In fact, some have questioned whether there is any benefit of axillary evaluation in elderly women at all, particularly in the presence of endocrine-responsive disease. The International Breast Cancer Study Group compared the outcome of axillary clearance versus no

clearance in women older than 60 years (median age, 74 years) with clinically negative, operable breast cancer. All women with endocrine-responsive breast cancer received 5 years of tamoxifen. Although axillary relapse was not the primary endpoint, the results were reassuring in this subgroup, showing a relapse rate of ~2% after 5 years of follow-up. Avoiding axillary clearance was associated with an improvement in early quality of life measures (391). A nonrandomized, retrospective study of elderly patients with clinical T1N0 disease treated by surgery and adjuvant tamoxifen with or without axillary lymph node dissection (ALND) showed no difference in OS after a median follow-up of 15 years. The axillary recurrence rate, however, was 5.8% in the group with no ALND compared to 0% in the group with ALND. No data are available regarding quality of life (392).

The recent publication of the ACOSOG Z-0011 trial has called into question the routine use of completion ALND in patients with SLN-positive disease. Women with one or two positive SLNs were randomized to no ALND or ALND with removal of at least 10 nodes. All patients underwent BCS with WBRT. The trial closed prematurely prior to full recruitment. Axillary recurrence rates were 0.9% in the SLN-alone group and 0.5% in the SLN plus ALND group, with no differences in distant recurrence or OS. While some still consider a sentinel lymph node dissection (SLND) followed by a completion ALND in patients with SLN-positive disease to be both useful and the standard of care for all patients (393), the omission of a SLNB and/or completion ALND may be reasonable in some elderly patients since ALND does not appear to affect breast cancer mortality and symptomatic axillary recurrences are rare. Furthermore, particularly in patients with endocrine-responsive disease, the information gained by a sentinel node biopsy is unlikely to have a significant impact on systemic treatment recommendations.

Radiotherapy

While the role of postoperative radiotherapy in decreasing local control following BCS has been well established, recent retrospective and prospective trials have evaluated the benefit in older women. While the omission of WBRT after BCS in elderly patients remains controversial, recent data suggest clinical circumstances in which WBRT may be safely avoided, particularly as it appears that despite a benefit in terms of locoregional recurrence, there is no obvious benefit in terms of OS. The CALGB 9343 trial randomized women 70 years or older with a clinical stage 1, ER+ breast cancer to lumpectomy plus tamoxifen with or without WBRT (394). At completion of 5-year median follow-up, the locoregional recurrence was 1% among patients receiving WBRT compared to 4% for those who did not receive WBRT. No OS difference was noted. Despite a lower beneficial therapeutic margin, the subset of patients who underwent radiotherapy still had a 3% lower risk of breast recurrences. The United Kingdom START trials (317,395) and a Canadian trial (316) have shown equivalent local control for standard WBRT and a hypofractionation schedule, and included a substantial number of elderly patients. Similar results were reported in a nonrandomized series of elderly patients (396).

While there may be a group of women whose margin of therapeutic benefit for postoperative radiotherapy is small enough that radiation can be safely omitted, currently, breast irradiation following BCS remains the standard of care. The decision to forego radiation therapy must take into account the best prognostic estimates and balance carefully a patient's life expectancy with the risk of serious adverse events from radiotherapy. Current trials evaluating IORT and APBI, such as the NSABP B-39 trial, may help to define better the options of postoperative radiotherapy for elderly patients. Additional data are expected following analysis of the PRIME II trial, which is evaluating the

effect of WBRT omission following BCS and endocrine therapy in patients (≥ 65 years) with T1–2 (≤ 3 cm), node-negative disease on ipsilateral breast recurrence rates, regional recurrence rates, contralateral recurrence, distant metastases, DFS, and OS (<http://homepages.ed.ac.uk/prime/prime2.html>).

Systemic Therapy

The confirmed benefit of adjuvant hormonal therapy for endocrine-responsive breast cancers is of particular relevance of elderly patients given that ~80% older women have ER+ cancers. Despite this, serious toxicities of tamoxifen may include rare cases of endometrial cancers and an increase in thromboembolic disease. With this in mind, it is notable that patients with small (<1 cm), node-negative tumors with other serious comorbid conditions and a life expectancy of less than 10 years are unlikely to benefit significantly from endocrine manipulation (397). More recently, the Danish Breast Cancer Cooperative Group study identified a subgroup of patients who might not benefit from adjuvant systemic therapy (398). In the absence of any systemic treatment, women aged 60 to 74 years with small (<1 cm), node-negative, endocrine-response, grade 1 ductal carcinomas or grade 1 or 2 lobular carcinomas did not demonstrate any increase in mortality compared to age-matched controls. In this patient population, it seems reasonable to omit endocrine therapy altogether.

Until recently, tamoxifen was the most commonly used hormonal treatment for ER+ breast cancers. However, data from the ATAC trial confirmed a DFS advantage for anastrozole over tamoxifen and a longer time to recurrence (399). In addition, anastrozole was associated with fewer thromboembolic and ischemic cerebrovascular events, and less endometrial cancer and vaginal bleeding, but a greater incidence of bone loss. Two analyses specifically reported on the outcomes following treatment with aromatase inhibitors among older women. The MA.17 trial evaluated the additional advantage of extended letrozole after 5 years of tamoxifen and demonstrated no additional benefit among women older than 60 years. The Breast International Group (BIG) I-98 trial compared letrozole with tamoxifen and showed a significant benefit in favor of letrozole (264). The study confirmed a higher incidence of bone loss and fractures. Thus in regards to elderly women who are at increased risk of osteoporosis and bone fractures, the long-term risks of aromatase inhibitors may be significant and must be taken into account when recommending adjuvant endocrine therapy.

Despite an overall favorable biologic profile in breast cancer in the elderly, a significant number of women have a substantial risk of recurrence and should be considered candidates for chemotherapy. Approximately 20% of elderly women evaluated in the SEER registry are diagnosed with node-positive cancers, and 10% to 25% have other poor prognostic features (397). Retrospective analyses of the SEER database have reported a statistically significant reduction in all-cause mortality of 15% to 28% among elderly women with ER- cancers treated with chemotherapy, particularly node-positive patients (400,401). Most experts suggest limiting chemotherapy to elderly women with HR- tumors that are considered high risk and whose life expectancy exceeds 5 years. Few women with node-negative, HR+ breast cancers are likely to benefit from chemotherapy. Newer gene-based risk assessment tools may help to distinguish those women with node-negative tumors whose risk is sufficiently high enough to warrant chemotherapy.

The optimal chemotherapy regimen, dose, and schedule for elderly patients remain undefined. CMF has been studied in this population and is reasonable, but it may be tolerated poorly and anthracycline-related toxicity may be an issue for elderly patients (379). In a retrospective observational study, docetaxel and cyclophosphamide treatment was determined to be feasible

(402). This regimen was shown to be superior to doxorubicin and cyclophosphamide in terms of DFS and OS (216). When combined with chemotherapy, trastuzumab has been shown to significantly improve the chances of cure among women with *HER2/neu* overexpressing tumors. As the number of long-term survivors of breast cancer increases, it remains important to identify and minimize the late effects of treatments. Cardiac toxicity is a significant side effect of trastuzumab and may be compounded by the joint use of anthracycline-based chemotherapy. Recent studies evaluating newer nonanthracycline regimens may change standard regimens, and incorporating these regimens with biologic agents such as trastuzumab may lead to improvements in survival while decreasing the cardiac toxicity associated with combined anthracycline and trastuzumab therapy. Currently, there are no data available for treatment with trastuzumab alone in patients who are poor candidates for chemotherapy, although the 2011 St. Gallen consensus states that if chemotherapy cannot be given, it may be reasonable to give trastuzumab alone (403).

Despite competing comorbidities, breast cancer is the direct cause of death for a substantial number of older patients, and up to 40% of women age 80 years or older at diagnosis die as a direct result of their breast cancer (383). Approximately 30% of older patients present with an aggressive biologic phenotype characterized by negative ER/PR expression. To what extent undertreatment of these patients based on an underestimation of life expectancy and treatment-related efficacy is the cause remains unclear. Surgical management of these patients is typically the same as in younger patients. While the absolute benefit of adjuvant radiotherapy may be limited, the current data demonstrate similar relative benefits to adjuvant radiotherapy, in the absence of endocrine-responsive disease; the option of chemotherapy needs to be discussed with the patient. The decision to forego or proceed with radiotherapy and/or chemotherapy must take into account both the tumor characteristics and the ensuing risk of relapse, as well as the patient's overall functional status and competing comorbidities. Extrapolation from earlier trials regarding the potential benefits or toxicity of chemotherapy is complicated by the small number of elderly patients accrued to these trials. Furthermore, in earlier trials that included elderly patients, inherent biases resulted in the recruitment of very "fit," or healthy, patients. Thus how these data may relate to patients who are less fit is unclear.

Disparities in Breast Cancer

Despite significant advances in the diagnosis and treatment of breast cancer, which have resulted in continued improvements in survival rates and overall outcomes, there exists a vast body of literature highlighting disparities in the mortality burden among population subsets. While the incidence rates for breast cancer in African-American (AA) women are lower than Whites (113 vs. 123.5 per 100,000), mortality rates are disproportionately higher among AA women (33 deaths vs. 23.9 per 100,000 cases) (404). Similar patterns have emerged among the Latina population, where breast cancer is now the leading cause of cancer death.

A variety of factors have been proposed to explain this difference in breast cancer outcome, including variations in access and adequacy of medical care, differences in breast cancer risk factors, and differences in genetics and biology. In fact, health insurance coverage and socioeconomic status is an important factor in determining health care outcomes in general, but it does not appear to be the only explanation for ethnicity-related outcome disparities with regards to breast cancer. Newman et al. conducted a meta-analysis of studies reporting on survival of AA versus White breast-cancer patients (405). After adjusting

for socioeconomic status, age, and stage of diagnosis, they found that AA women still experienced a higher risk of mortality, with a mortality hazard ratio of 1.27 (95% CI, 1.18–1.38). Similarly, Field et al. evaluated survival among AA and White breast-cancer patients receiving care through the Cancer Research Network, which covers patients using managed care health plans (406). Despite similar health coverage and access to care, 5-year survival was lower for AA women (74% vs. 82%). They concluded that among women with invasive breast cancer, being insured and having access to medical care does not eliminate the survival disparity for AA women. Therefore, it appears that inequalities in access to health care, while a reality for many AA women in the United States and likely partially accounting for differences in outcomes, are not solely responsible for the racial disparities evident among women diagnosed with breast cancer.

Another argument is that differences in tumor biology or other extrinsic factors account for a significant proportion of the disparity evidenced among different racial/ethnic groups (407). Invasive ductal carcinoma remains the most common histologic type of breast cancer identified, regardless of ethnicity. However, reports suggest a higher frequency of aggressive subtypes among AA women, such as basaloid and IBC (342,408,409). In a population-based study of the California Cancer Registry, Bauer et al. demonstrated that the greatest risk factor for a triple-negative subtype was age younger than 40, Black race, and, to a lesser extent, Hispanic race (66). Elledge et al. identified no significant differences in the frequency of HER2+ breast cancers among different racial groups (407). A study comparing a group of Hispanic women to White women reported that Hispanic women presented more often with larger, triple-negative cancers at a younger age, despite equal access to health care (410). Others have demonstrated similar findings (411,412).

Studies evaluating the incidence of *BRCA1* and *BRCA2* mutations in the Hispanic population have been reported, and among non-White minorities, Hispanics with breast cancer have the highest reported incidence of pathogenic *BRCA1* mutations (413). Recently, Weitzel et al. reported on a large deletion identified in 5 unrelated Mexican families (414). A large multiplex panel that tests for 18 mutations in *BRCA1/BRCA2* is currently being developed for testing in Hispanic patients (415). For their part, the frequency of *BRCA1/BRCA2* mutations among AAs appears to be lower than that observed among White women, Ashkenazi Jewish individuals, and Hispanic women (413,415).

Disparities in the delivery of adjuvant chemotherapy to eligible patients may account for disparities among AAs, and studies do show a disturbing trend. White et al. (416) reported in 2003 that among 1,263 patients with node-positive breast cancer eligible for chemotherapy, 85.3% of White women received the indicated treatment, compared to 78.7% of AA and Latina patients. More recently, Bickell et al. (416,417) reported data from 6 New York City hospitals and found that AAs were twice as likely to be undertreated with regards to either chemotherapy, radiation therapy, and/or endocrine therapy compared with White patients. Others have reported similar findings (418).

Disparities also appear to exist in surgical management of breast cancer. In their review of the SEER database (417,419), AA breast cancer patients were 36% less likely to receive sentinel node biopsy compared with White breast-cancer patients. This is similar to that which was reported by Bickell et al. Several groups have reported lower rates of breast reconstruction following mastectomy (419,420). In their analysis, Tseng et al. not only noted a lower pattern of referral for breast reconstruction, but they also reported lower rates of reconstruction being offered if indeed a consultation took place. The extent to which these decisions reflect patient preferences is unknown.

Despite this, most studies comparing BCS between AA and White women have shown equal rates of BCS. Similar studies are unavailable in Hispanic women. There are concerning data, however, regarding inadequate margin control in lumpectomy specimens, failure to receive postoperative radiation therapy, and inequalities in axillary staging procedures (421).

Effective evaluation of the determinants of racial disparities in breast cancer treatment will require adequate participation in randomized clinical trials. Currently, the percentage of AAs, Latinas, and other ethnic groups in multicentered trials is low. In their study, Simon et al. demonstrated that only 21% of AA patients were offered a clinical trial, compared to 42% of the White patients. That study did not control for trial eligibility. In their study evaluating barriers to enrollment of minorities onto clinical trials, Adams-Campbell et al. reported that among 235 AA patients with breast cancer, only 8.5% were eligible for trial participation. Most of these women were excluded due to comorbid disease.

There is one underlying assumption that is made as we strive to eliminate racial disparities in breast cancer treatment outcomes. That is, that equal treatments will yield equal results. Recent retrospective analysis of data from the NSABP trials seems to support this belief (422,423). A recent study from MDACC further supported this contention (424). Similar responses to neoadjuvant therapy were reported when comparing AA women to White women. Data from analysis of SWOG trials, on the other hand, showed that despite similar treatment with adjuvant therapy, AA women with node-positive breast cancer had higher mortality compared with White women, even when controlled for differences in socioeconomic status and ER status (425). A similar evaluation of Cancer and Leukemia group B (CALG-B) data showed a worse outcome on univariate analysis, but this did not persist on multivariate analysis (426), emphasizing the need for greater representation of different ethnicities in large, cooperative trials in order to address better the question of a differential response to treatment.

Documented racial disparities exist in the incidence, treatment, and outcomes of women with breast cancer. Of great concern, the mortality among AA and Latina women diagnosed with breast cancer exceeds that of White women, despite an overall lower incidence of disease overall. The determinants of these disparities are likely multifactorial, and despite numerous studies, they remain incompletely understood. Increasingly, studies point to a combination of variable access to care, resulting in more advanced stages at diagnosis, differing risk factors to breast cancer, and differences in genetics, biology, and treatment.

Summary

The field of breast oncology has evolved significantly, with gains made in prevention, screening, diagnosis, and management. All of these have led to a reduction in the mortality rate from breast cancer, with a resultant increase in the population who are considered breast cancer survivors. Despite this, multiple questions remain: how should new radiologic technologies, such as tomosynthesis, be incorporated into routine screening practice? Should breast MRI utilization be expanded to all women with a new diagnosis of breast cancer? How can we maximize the use of neoadjuvant chemotherapy in women with invasive disease? How should we treat patients who have persistent disease following primary chemotherapy? Is partial breast radiation as safe as whole breast radiation? These are only a few of the issues that oncology will need to address as we look forward into the future.

There is no one standard of care in the management of the patient with breast cancer. The indications for the use of

chemotherapy continue to evolve as evidence mounts that women with breast cancer cannot be considered one in the same. HR status can predict who will benefit from endocrine therapy, and appears to also predict who has little to gain from chemotherapy. Our current understanding of the treatment landscape in breast cancer has reinforced one point: that treatment must be individualized, especially since multiple options are considered reasonable. The evolution of breast cancer management will undoubtedly continue as researchers seek to define more targets for treatment and refine the appropriate therapies for the patient with breast cancer, tailored to hormone and HER2/neu status. Utilization of new technologies for treatment and follow-up will be better characterized, such as the use of APBI or the use of circulating tumor cells. Hopefully, we will continue to improve the outcomes for our patients with breast cancer, and increase the chances more women will be cured.

KEY POINTS

1. Technological advances have improved our ability to classify breast cancers, going from histopathologic characterization of a tumor into the genomic signature that the tumor carries. Luminal, basaloid, and HER-2 overamplified breast cancers are a part of this new classification, which may yet help determine the best way to individualize treatments.
2. The mammogram remains the key screening test for women. Ultrasound is useful in distinguishing a benign versus malignant lesion or in the evaluation of a non-mammographically apparent mass. Breast MRI is indicated in selected populations as a screening tool and as an adjunct to mammography for treatment planning purposes.
3. Mastectomy and breastconservation surgeries achieve equivalent outcomes, the latter of which is possible with the use of adjuvant radiation therapy. Sentinel node biopsy is the standard of care in the surgical management of the new patient with breast cancer, with a clinically negative axillary examination. Completion axillary dissection in those patients with a positive sentinel node remains standard of care, though considerable controversy exists as to whether this standard must be applied uniformly.
4. The adjuvant treatment of breast cancer must be individualized. While chemotherapy plays an important role in the adjuvant setting, we are recognizing the variable response and benefits that can be achieved, particularly in those women who are ER+ and even in those women who are HER2/neu-. Patients with high-risk node-negative (1 cm or more if ER-, 2 cm or more if ER+ or node-positive breast cancer who are HER2/neu+, warrant treatment with an anthracycline, taxane treatment and adjuvant trastuzumab therapy.
5. Endocrine therapy remains the most potent agents for women with ER+ breast cancer.
6. Radiotherapy achieves a reduction in local recurrence when used as an adjuvant modality. This becomes important as evidence indicates that local recurrence is a predictor of mortality from breast cancer.

The treatment of breast cancer calls for a coordinated multimodality approach that ensures all aspects of the disease are being expeditiously and appropriately addressed.

Management of Infections
in Patients with Gynecologic
MalignancyAMAR SAFDAR ■ KENNETH ROLSTON ■ GENEVIEVE L. BENNETT
ROBERT PRESS ■ DONALD ARMSTRONG

Patients with gynecologic cancer are susceptible to infections. The risk of developing an infection can arise from a number of factors that may relate to the neoplasm and antineoplastic therapy, or both. Tumor encroachment and invasion of adjacent structures, necrosis of expanding tumor mass, surgical tumor excision, and removal of internal organs including lymph nodes and diversion procedures that disrupt protective barriers in the lower and upper female reproductive tract are a few such causes. Patients with these malignancies may also be susceptible to a host of infections due to presence of drug- or radiation-induced mucositis, severe neutropenia, long-term sequelae of prior abdominopelvic radiation therapy, and presence of indwelling foreign devices (1,2).

The wide spectrum of causative microorganisms most frequently arises from endogenous vaginal, urethral, and intestinal tract colonization with bacteria and *Candida* species. The normal aerobic and anaerobic vaginal bacterial flora may be altered in patients undergoing antimicrobial and antineoplastic therapy. Among factors that influence changes in colonization are hormonal dysfunction, factors influencing alteration in the composition of mucosal secretions including innate immune functions, frequent exposure to broad-spectrum antimicrobial agents, antineoplastic drug and radiation therapy, instrumentation and prolonged, often multiple hospitalizations. In a recent report, however, patients receiving external-beam radiotherapy for gynecologic malignancy did not experience changes in aerobic microflora in the vagina, cervix, or rectum (3,4). Whereas a significant growth in vaginal yeasts occurred during the first 2 weeks after radiation therapy commenced; *Candida albicans* and *Candida tropicalis* were prominent. The increase of vaginal growth of *Candida* species returned to preradiation levels after 4 weeks (5). Exposure to health care facilities, especially centers that care for immunocompromised oncology patients, has been recognized as a major influence, albeit transient in most instances, in promoting change in cutaneous, orointestinal, and genitourinary microflora. The changes in vaginal and lower urinary tract microflora occur less commonly, even in patients following repeated exposure to the hospital environment, and are often limited to patients who undergo instrumentation. The health care-associated microorganisms are frequently less susceptible to commonly prescribed antibiotics, and optimum selection of antimicrobial drugs poses a daunting challenge. It is, however, important to appreciate that changes in a host's microflora are in most cases transient and restitution of normal intestinal and vaginal flora occurs once factors promoting the change have been removed.

The female genital tract is rich in anaerobic microflora. *Peptococcaceae* are prominent in the normal vaginal bacterial flora. Quantitative vaginal cultures in recent studies showed that anaerobic bacteria outnumbered aerobic bacteria by nearly 10:1;

peptococci, *Lactobacillus*, *Corynebacterium*, *Eubacterium*, and *Bacteroides* species are frequently isolated (6). *Escherichia coli*, *Klebsiella* species, and *Enterobacter* species are the aerobic Gram negatives, and streptococci, enterococci, and coagulase-negative staphylococcus are gram-positive bacteria isolated from the lower female genital tract. These organisms provide an important reference to local and invasive infections seen in patients undergoing treatment for gynecologic malignancy.

This chapter provides an overview of infections encountered in patients receiving treatment for cancers involving the female reproductive system. A detailed review of specific diseases such as postsurgical abdominopelvic infections, febrile neutropenia, and bacteremia is presented. A focused discussion regarding the changing epidemiology of causative organisms, the increasing rate of infection due to drug-resistant organisms, and an update on new antimicrobial agents is briefly discussed.

PATIENTS WITH FEVER

The factors that increase the risk for infection are shown in Table 29.1. Knowledge of underlying predisposing factor(s) is necessary in the selection of appropriate empiric therapy. Antibiotic prophylaxis and/or recent treatment with broad-spectrum antimicrobial drugs have been associated with the risk of infection(s) due to non-drug-susceptible microorganisms, including systemic candidiasis. Awareness of specific cancer and cancer-therapy-associated risks and the host's underlying immune dysfunction may allow for proper selection of empiric antibiotic therapy in critically ill patients prior to the results of diagnostic microbiologic and radiographic studies are known. It is important to note that patients with gynecologic cancer may have a high risk of polymicrobial infections due to the presence of physiologic microflora resulting from anatomic proximity to the lower intestinal and urinary tracts. In certain infections, such as deep-tissue abscess, cellulitis in patients with chronic fistula tract, presence of large necrotic tumor, and history of multiple recent instrumentation, the probability of polymicrobial infection remains high (7). Furthermore, in patients with a known anaerobic bloodstream infection, concurrent bacteremia due to aerobic organism(s) is not uncommon (7). Patients with advanced cancer, history of radiation therapy, and extensive pelvic surgery may develop obstruction to the pelvic venous and lymphatic flow. The aberration in physiologic/anatomic defenses and stagnation heightens the risk for cellulitis, abscess formation, and septic thrombophlebitis. Furthermore, these factors also unfavorably influence response to antimicrobial therapy. Several Comprehensive Cancer Centers and other institutions that care for large numbers of patients with cancer have

developed Infectious Disease consultative services with a special interest and expertise in infections seen in this high-risk patient population. Table 29.2 provides a breakdown of the various infectious and noninfectious causes that resulted in Infectious Disease consultation requests from the gynecologic oncology clinical service at the MD Anderson Cancer Center.

TUMOR RELATED

Tumor-associated infections are dependent on the anatomic site, type, and extent of tumor involvement. In patients with an early-stage, locally involved cancer such as stage I cervical cancer, most infections remain localized to the vagina, whereas in

patients with advanced cervical cancer, infections may involve the uterus, fallopian tubes, ovaries and other deep pelvic structures, and retroperitoneum. Infections may present as tubo-ovarian or deep pelvic abscess, endometritis, and less frequently seen pyometra (Figs. 29.1, 29.2, and 29.3). Extension of these infections to adjacent structures may present as ascending pyelonephritis, rectal abscess, and complicated peritonitis, which are often serious requiring surgical debridement or intervention by invasive radiology (8,9). It is also important to note that an infection may be the primary presentation of an undiagnosed malignancy involving the female reproductive tract. In a study of postmenopausal women who presented with tubo-ovarian abscess, nearly half of these patients were subsequently diagnosed with a gynecologic malignancy (10). Therefore, a thorough investigation for possible underlying cancer should be considered in postmenopausal women or those in the absence of sexually transmitted diseases who present with tubo-ovarian abscess or pyometra.

In a large study conducted at the MD Anderson Cancer Center in the 1970s, septicemia, pneumonia, and peritonitis in patients with gynecologic cancer were associated with high infection-associated mortality (11). In the last 2 decades, in patients at an increased risk for infections, early diagnosis, identification of factors associated with poor treatment outcome, empiric therapy with new generation broad-spectrum antimicrobial drugs, advances in antineoplastic and target-centered radiation therapy, and improved surgical techniques have substantially improved outcomes. The recent favorable outcomes

FIGURE 29.1. A 73-year-old woman with endometrial cancer presented with pelvic pain, fever and vaginal bleeding. Axial CT scan performed with enteric and IV contrast demonstrates a markedly distended endometrial cavity containing fluid (*). There is air also present, with an air-fluid level (arrow). In a febrile patient, this is highly suggestive of infection/endometritis. At D&C, blood and pus were drained from the uterine cavity compatible with pyohematometra.

FIGURE 29.2. A 46-year-old woman with cervical cancer presented with pelvic pain and fever. Sagittal contrast enhanced CT image demonstrates a large cervical mass (*). There is obstruction of the endometrial cavity which is mildly distended and contains fluid and air (arrow), compatible with infection/pyometra.

FIGURE 29.3. A 40-year-old woman with cervical cancer presented with fever, left lower quadrant pain and diagnosed with tubo-ovarian abscess. Axial contrast enhanced CT scan demonstrates a complex multiloculated mass with thick septations (white arrow) to the left of the uterine fundus (U). There are inflammatory changes in the pelvic fat (black arrow).

for serious systemic bacterial and *Candida* species infections are in most part due to the availability of well-tolerated broad-spectrum antimicrobial drugs. The recent emergence and spread of multidrug-resistant (MDR) organisms, however, may mitigate these advances, and even patients with solid-organ cancer with limited immune suppression, life-threatening septicemia, pneumonia, peritonitis and abdominopelvic infections may mimic the antibiotic nascent era (11).

SURGERY RELATED

Patients undergoing surgery for cervical cancer have a higher rate of infectious complications, compared with patients with endometrial cancer who tolerate surgery better and have fewer infections during the early and late postoperative period (12). Pelvic exenteration is performed in patients with advanced and/or treatment refractory cervical and upper reproductive tract malignancies. Infections remain as serious complications following pelvic exenteration; early postsurgical wound infection and wound dehiscence are not uncommon (13,14). Urinary tract infections frequently occur in patients with urinary fistula and/or those who develop urethral obstruction. Studies show that greater than 40% of patients undergoing pelvic exenteration for gynecologic and rectal cancer had urinary tract infection and wound dehiscence, or both (13). Late infections such as ascending pyelonephritis may be serious, as they frequently recur and are usually seen in patients with irreparable structural damage to the urinary reservoir such as those with a neobladder or with stenosis of the urethra or surgical anastomosis site. Ureterointestinal fistula; stones in the urinary reservoir; and surgical, radiation, or chronic/recurrent infection/inflammation-induced narrowing all contribute to increased risk of infections, and unless the anatomical abnormality is corrected, these patients remain at increased risk for recurrent urinary tract infections and complications arising from prolonged systemic antibiotic therapy and repeat hospitalizations. Empiric therapy includes adequate coverage for possible polymicrobial infection, and the choice should include drugs that provide adequate coverage for enteric coliforms, enterococci, including vancomycin-resistant *Enterococcus* species, especially in patients with known prior intestinal or genitourinary tract colonization due to these drug-resistant bacteria and/or receiving care at centers with known high prevalence for these pathogens (15). As most infections in this setting may also have an anaerobe as a copathogen, even in patients with negative microbiologic evidence of anaerobic infection, antibiotic selection should entertain nonisolated anaerobic bacteria. We recommend secondary suppressive antimicrobial therapy in patients with recurrent deep pelvic infection to reduce morbidity and subsequent hospitalization and surgeries. It is critical to select high-risk patients judiciously so patients are not given prolonged courses of broad-spectrum antibiotics, which is the single most important factor in promoting selection for or, less commonly, development of *de novo* drug-resistant bacteria and fungi.

Infections remain the main concern in patients following radical vulvar resection and inguinal lymph node dissection. In 67 patients undergoing 112 inguinal lymphadenectomy, early postoperative cellulitis is noted in nearly one-third of patients undergoing inguinal lymphadenectomy, and in over 20%, early surgical wound breakdown also occurred (16). Furthermore, they observed late surgery-site cellulitis in patients with chronic lymphedema, whereas, in most patients the surgical wound was not compromised (16).

Wound Infection

Infected surgical wounds in patients following female genital tract surgery include *Staphylococcus aureus*, including MDR

or semisynthetic penicillin resistant *S. aureus* (MRSA) obtained from health care microflora (health care associated [HA]) or community acquired (CA)-MRSA, which has now become the leading source of MRSA infections in the United States and globally. *Streptococcus* species (group A, B, C, non-Enterococcus D and G) are also common pathogens in this population, and nearly one-third of infections, especially those with involvement of the lower intestinal tract and urinary tract, are less likely to be monomicrobial.

In certain subpopulations of patients who have been receiving systemic corticosteroids for extended periods, patients with morbid obesity, malnutrition, cancer related cachexia and those with poorly controlled diabetes mellitus have a higher risk of developing postoperative wound infections. Coagulase-negative *Staphylococcus*, *Streptococcus* species, *S. aureus*, enteric gram-negative bacteria, and *Bacteroides* species are potential pathogens.

Patients who have a complicated hospital course following surgery may develop infections due to organisms acquired from the health care microenvironment. In critically ill patients, infections are treated empirically, and the spectrum of causative organism(s) may not be available at the time of medical decision making. Knowledge of regional and institutional prevalence of drug-resistant organisms is required in prescribing an appropriate treatment regimen. The empiric therapy in patients with prolonged hospitalization and anatomic abnormalities such as enterourethral, entero- or rectovaginal, or enterovesicular fistula increases the probability of recurrent infection due to resistant HA-gram-negative bacteria, such as *Pseudomonas* species, and extended-spectrum beta-lactamases-producing and carbapenemases-producing *Enterobacteriaceae*, such as *E. coli* and *Klebsiella pneumoniae*. Other nonfermentative gram-negative bacteria such as nosocomial *Acinetobacter* spp. and *Stenotrophomonas maltophilia* are often resistant to a wide variety of commonly used broad-spectrum antibiotics; successful treatment for MDR bacterial disease remains a consternant task (17,18).

Intra-abdominal and Pelvic Abscess

An infected collection within the peritoneal cavity may develop as a consequence of breach in the physical barriers resulting from tumor progression or tumor necrosis and may also occur in patients undergoing instrumentation, or as a consequence of reconstructive surgery and implantation of prosthetic devices. The secondary seeding of the intraperitoneal tumor mass in patients with bloodstream infection arising from a different primary source, such as the urinary tract, antineoplastic therapy-induced orointestinal mucositis, or indwelling vascular device may also occur. The spectrum of causative organisms includes enteric bacteria such as *E. coli*, *Enterococcus*, *Staphylococcus* species, *Bacteroides*, and other anaerobes. *Candida* species infection is less frequent in nonneutropenic patients, although patients with high yeast counts in multiple body sites referred as high *Candida* colonization index, exposure to prolonged broad-spectrum antibiotics, poorly controlled diabetes mellitus, systemic corticosteroid use, as well as stay in critical care units and presence of foreign devices may increase the risk for tissue invasive candidiasis.

Hematogenous or direct seeding of the retroperitoneal space may lead to paraspinal and psoas abscess; these infections escape early detection as patients may not have high-grade fever, and increase in chronic low back pain remains subject to interpretation. In the absence of a direct extension from the intestinal or urinary tract, these retroperitoneal infections are usually monomicrobial, and diagnosis requires prompt computed tomography or magnetic resonance imaging scans and aspiration of the infected collection (Figs. 29.4 and 29.5). In tuberculosis endemic regions, *Mycobacterium tuberculosis* must

FIGURE 29.4. A 52-year-old woman with fallopian tube carcinoma initially diagnosed as tubo-ovarian abscess. She presented to the emergency department with left lower quadrant pain, and fever. **A:** Transvaginal ultrasound demonstrates a complex left adnexal mass with a tubular in configuration fluid-filled component (arrow) and a solid component (*). **B:** Additional image demonstrates a fluid-debris level within this mass (arrow). Initially, this was thought to represent a tubo-ovarian abscess; however, the patient had no risk factors for pelvic inflammatory disease. At surgery, fallopian tube carcinoma was found.

be considered in determining the etiology of these infections, especially in patients in whom the vertebral column is involved.

Pelvic abscesses that develop after instrumentation or following surgery are often polymicrobial, and treatment is directed toward normal intestinal tract and cutaneous microflora.

Peritoneal infections following bowel perforation, anastomotic leaks, or fistula tracts may present with fever, abdominal pain, and fistula drainage and/or surgical wound dehiscence. Most infections, as expected, are polymicrobial, and *Enterobacteriaceae*, *S. aureus*, *Streptococcus*, and *Enterococcus* species including vancomycin-resistant strains are frequently encountered. *Bacteroides fragilis* and *Clostridium* species are common anaerobes; *Fusobacterium*, *Peptostreptococcus*, and *Eubacterium* occur less commonly. Patients with peritoneal infections following surgery involving the nonsterile bowel and lower genitourinary tract may also have an increased risk for *Pseudomonas* species infection involving the deep pelvic and lower abdominal tissue and/or organs.

CHEMOTHERAPY AND RADIATION RELATED

Patients receiving chemotherapy may have an increased risk of infection; neutropenia for less than a week increases risk for systemic bacterial infections due to *S. aureus*, *Pseudomonas*, *E. coli* and other coliform bacteria. Patients who remain neutropenic

FIGURE 29.5. A 48-year-old woman with cervical cancer presents with left flank pain and fever: **A:** Sagittal gray-scale ultrasound image of the left kidney demonstrates marked hydronephrosis compatible with ureteral obstruction secondary to the patient's cervical neoplasm. There is echogenic debris present in the dilated collecting system (arrows) compatible with pus in the setting of pyonephrosis. **B:** Axial contrast-enhanced CT scan in the same patient demonstrates the enlarged left kidney with hydronephrosis (arrow). There is a delayed nephrogram compared with the right, compatible with obstruction. The left nephrogram is also heterogeneous and there is perinephric inflammatory change compatible with pyelonephritis. The right kidney is normal with the exception of a small cyst.

for longer than 5 to 7 days are also at increased risk for developing tissue-invasive *Candida* species infection (1,2). Disruption of orointestinal and genitourinary tract mucosa compromises an important barrier in the prevention of bacterial and fungal invasion. In patients with severe treatment-induced mucositis, α -hemolytic streptococcal and anaerobic septicemia may lead to devastating consequences, including rapidly progressive multiorgan failure, disseminated intravascular coagulation, hemodynamic collapse, and death (19).

Radiation therapy in patients with vulvar, vaginal, and cervical cancer causes microvascular damage to the tissue and may lead to difficult-to-treat intestinal, vaginal, and urologic complications.

Increased doses of radiation for gynecologic cancer have been associated with improved cancer-free survival (20). However, with increased radiation dose, the rate of complications has also risen (21). Noninfectious complications arising from high-dose radiotherapy include damage to the organs in radiation field, including necrosis of tissue and bone, fistula formation, enteritis, proctitis, aseptic degenerative arthritis of pelvic, and sacroiliac joints increasing the risk for pathologic fracture. Radiation-induced fibrosis may result in vaginal, rectal, and ureteric stenosis, and predisposes to secondary infection due to stagnation and inadequate physiologic drainage (22). In rare cases, patients with radiation-induced necrosis of pelvic bones may present with osteomyelitis; for these patients, a challenging

FIGURE 29.6. A 53-year-old woman with recurrent papillary serous carcinoma of the ovary with serosal bowel implants undergoing treatment with intraperitoneal chemotherapy presents with abdominal pain, vomiting and fever: **A:** Upright abdominal radiograph demonstrates large amount of free intraperitoneal air with air-fluid level due to the presence of ascites fluid (arrows). Multiple dilated air-filled loops of bowel are noted. Intraperitoneal chemotherapy infusion catheter is in place with port in left upper abdomen. These findings are compatible with perforated viscus. **B:** Axial contrast enhanced CT scan in the same patient demonstrates a large amount of free intraperitoneal air (white arrow) and ascites fluid (black arrow). There are multiple dilated loops of bowel. There is a mottled gas collection in the right lower quadrant posterior to the cecum (open white arrow). At surgery, the cecum was found to be perforated. **C:** Large loculated fluid and gas-containing collection in the pelvis is compatible with an abscess (*). The chemotherapy infusion catheter is visualized at the posterior wall of the abscess (black arrow).

and multifaceted treatment approach is needed for successful outcomes (23) (Fig. 29.6). A patient with osteomyelitis in the setting of radiation-induced bone necrosis may need extensive surgical debridement and an appropriate selection of antibiotics for a prolonged period. The excisional defects create additional complexity due to placement of prosthetic or autologous or cadaveric biologic grafts. A high clinical suspicion remains critical in the timely diagnosis of radiation-related infectious and noninfectious complications.

Bacteremia

Most hematogenous bloodstream infections in adult neutropenic cancer patients are due to coagulase-negative *Staphylococcus*, viridans streptococci, *E. coli*, *Pseudomonas aeruginosa*, and *S. aureus* observed in prospective case-controlled study (24). In patients with solid-organ cancer, *E. coli* and coagulase-negative *Staphylococcus* account for nearly 40% of bacteremia, whereas *Pseudomonas*, *S. aureus*, and enterococcal bloodstream infections each account for 10% or less (25). *Klebsiella* species, other *Enterobacteriaceae*, and *S. maltophilia* are a serious concern and may become prominent bloodstream infections in certain geographic regions.

Cancer patients with bacteremia who present with extensive tissue involvement/infection are significantly less likely to respond to antimicrobial therapy (26). Other factors associated with poor prognosis in bacteremic adult patients with an underlying malignancy include shock, infection due to multidrug-resistant bacteria, and *Pseudomonas* and *Clostridium* species infection (26).

Bacteroides and *Clostridium* species are the most frequent cause of anaerobic bacteremia, which is most frequently seen in patients with abdominal and pelvic malignancy (26,27). In cancer patients with nonsporulating anaerobes bacteremia, *B. fragilis*, and *Fusobacterium* are isolated more frequently compared with *Peptostreptococcus* and *Eubacterium* species (28). Polymicrobial infections are more frequent in patients with anaerobic bacteremia compared with aerobic bacterial infections. *E. coli*, *Pseudomonas*, *Klebsiella* species, and among gram-positive cocci, *Streptococcus*, *Enterococcus*, and *Staphylococcus epidermidis* may accompany anaerobic bloodstream infection (28). Concurrent candidemia is uncommon in patients with bacteremia due to anaerobic bacteria, unless patients have (a) high *Candida* colonization index, (b) indwelling intravascular catheter, (c) are receiving care in critical care unit, or have (d) poorly controlled diabetes, (e) parenteral nutritional support, or (f) severe and prolonged treatment-induced neutropenia. Over 90% of patients with nonsporulating anaerobic bacteremia may also have a deep-tissue abscess (28). The authors suggest that all patients with gynecologic malignancy who present with anaerobic bacteremia be thoroughly evaluated for an infected abdominopelvic or pelvic collection, which may not be clinically apparent at the time of initial presentation.

Hematogenous *Clostridium* species infection is often seen in patients with gastrointestinal or genitourinary cancer, and acute leukemia (29). Nearly one-third of patients with bacteremia with *Clostridium* species alone and nearly half with polymicrobial infection present with septic shock (29). *Clostridium perfringens* is a common species, and *Clostridium septicum* is uncommon, albeit serious *C. septicum* infections are seen in patients with intra-abdominal neoplasms (29,30). Diffuse, rapidly spreading cellulitis involving the abdominal wall, groin, and upper thigh area, gas gangrene, and acute intravascular hemolysis indicate the possibility of clostridial infection (29). Early appropriate therapy remains critical in improved response and outcome for patients with deep-tissue anaerobic infection with or without accompanying bacteremia.

Febrile Neutropenia

The organisms associated with infections in patients with neutropenia are shown in Table 29.3. *Pseudomonas* spp. is a well-recognized cause of serious systemic infections in febrile neutropenic patients. The other nonfermentative gram-negative bacteria such as *S. maltophilia* have emerged and present as life-threatening pneumonia, bacteremia, or deep-tissue infection; these infections are commonly resistant to standard broad-spectrum antipseudomonal antibiotics, and despite appropriate therapy response may remain suboptimum (17). Patients with peripheral absolute blood neutrophil counts of less than 500 have significantly higher risk of serious infection, especially if the duration of neutropenia is more than 5 to 7 days (1,2). During the first 5 days of neutropenia, bacterial infections are prominent; if neutropenia extends beyond a week, invasive candidiasis becomes a concern; and in patients with greater than 2 weeks of profound neutropenia invasive mold infections such as aspergillosis may be occasionally encountered. In most patients with gynecologic malignancy, isolation of a mold even from sterile samples does not indicate invasive fungal disease; in patients with no known established predisposing factors (31), these saprophytic molds usually represent colonization or laboratory contamination (32).

Catheter-Related Bloodstream Infection

In patients with solid-organ cancer, nearly 70% of gram-positive bacteremias are associated with an infected indwelling vascular catheter; similarly, 60% of gram-negative bacteremias are also related to an infected catheter, whereas only 19% of

Table 29.3 Microorganisms Commonly Associated with Infection in Neutropenic Patients

Enterococcus spp. including vancomycin-resistant strains

Fungi^a

Candida spp. including *C. albicans*, *C. glabrata*, *C. tropicalis*, and *C. parapsilosis*

^aPatients receiving multiple courses of fluconazole therapy or prolonged antifungal suppression or prophylaxis are at higher risk for infections due to drug-resistant *C. glabrata* and *C. krusei*.

gram-negative bacteremias in patients with hematologic cancer is due to an infected catheter (33). Coagulase-negative *Staphylococcus* remains the most commonly isolated microorganism in blood cultures drawn from an indwelling central venous catheter and is frequently regarded as catheter-related bloodstream infection. Similarly, *S. aureus*, including MRSA bacteremia, may result from an infected indwelling catheter, and successful therapy requires selection of antimicrobial agents that penetrate the biofilm and are effective against the sessile nongrowth stationary phase of the bacteria (34). *S. aureus* bloodstream infections are associated with high rates of complications (35). Patients with solid-organ cancer with catheter-related *S. aureus* bacteremia have a fivefold higher probability of developing intravascular complications such as septic thrombosis and less commonly infective endocarditis (35).

Patients with gynecologic malignancy have a higher rate of postoperative infection, catheter malfunction, and unplanned catheter removal following external intravascular catheters compared with subcutaneous/implantable venous access devices (36,37). Nearly one-third of all intravascular catheters were associated with delayed complications in this cancer population; bacteremia was significantly more common in patients with nonimplantable (Hickman catheters) compared with implantable indwelling intravenous devices such as infusaport or peripheral access system ports (38).

IMPLANTABLE DEVICE INFECTIONS

Peritoneal, hepatic, and pleural implantable devices for delivering chemotherapy or drainage of recurring malignant effusions have been successfully used in the last 2 decades. These devices are well tolerated; major complications including bowel perforation are uncommon, and serious infections are seen in less than 5% of cases (39–44). Overall, infections are seen in less than 20% of cases. While serious infections including pocket infections are seldom noticed, when infections such as these do occur, they should be treated aggressively, requiring prompt removal of the infected reservoir and appropriate systemic antimicrobial therapy (39). Abdominal pain and chemotherapy-related discomfort remain as the major problems with these chemotherapy infusion devices.

Urinary Tract Infection

Patients with gynecologic cancer have an increased risk for urinary tract infection. The factors that promote infections are listed in Table 29.4. Nearly one-third of patients, while undergoing pelvic radiotherapy for gynecologic cancer, may have symptoms of urinary tract infection at the onset of therapy or develop infection during the course of radiation therapy (45). Despite appropriate therapy, infections may recur and require several courses of antibiotic therapy (45). Patients who have undergone pelvic exenteration remain at increased risk for ascending urinary tract infection (14); recurrent pyelonephritis in these patients leads to an increased risk of scarring and permanent renal damage. Older patients with advanced gynecologic and urologic malignancies are also recently being considered for pelvic exenteration surgery (46). In these and other patients with lower renal reserves, a severe episode of pyelonephritis may precipitate irreversible renal failure prompting prolonged renal replacement therapy. We suggest that in selected high-risk patients, preemptive antimicrobial therapy or even secondary antibiotic prophylaxis be considered after an episode of urinary tract infection, especially pyelonephritis.

Suppression of local immune surveillance and response to bacterial invasion

Mucosal damage and disruption

^a Patients undergoing routine replacement of percutaneous nephrostomy tubes may develop transient bacteremia in the event of prior colonization.

ANTIMICROBIAL AGENTS

It is important to refer to the spectrum of local and regional drug resistance among commonly encountered pathogens in selecting appropriate antimicrobials, especially when treatment is initiated empirically or in patients awaiting microbiologic drug susceptibility results.

SURGICAL ANTIMICROBIAL PROPHYLAXIS

Operative Site

Guidelines for the administration of antibiotics to uninfected patients undergoing pelvic surgical procedures were first proposed by Ledger et al. in 1975 (47). Prophylactic antibiotics are indicated for women undergoing pelvic surgery for malignancy. There have been few studies evaluating this prophylaxis

in such cases. Recently, cefazolin was showed to be inferior to cefotetan as a single-dose prophylaxis in women undergoing elective abdominal hysterectomy (48). A placebo-controlled trial showed that using a broad-spectrum cephalosporin plus beta-lactamase inhibitor significantly reduced the risk of major operation-site infection from 27% in patients not given antimicrobial prophylaxis, whereas none given antibiotic developed operative-site infection (49).

The overall postoperative infection rate has been as high as 46%, and surgical-site infection is seen in nearly one-fourth of patients (50). The risk of postoperative infection is adversely affected by prolonged duration of surgery for >5 hours, presence of remote infection at the time of surgery, and duration of hospitalization for longer than 3 weeks; in patients with all 3 risk factors the relative risk of infections increases to 7.3% compared with 3% in patients who have only one of these risk factors (50). Risk factors that have been associated with an increased incidence of infection in patients undergoing surgery for reproductive tract neoplasms include lower socioeconomic status, preoperative colonization, failure to administer perioperative heparin, obesity, advanced patient age, a longer operative period, and a longer hospital stay prior to surgery (51,52). Extent of surgery plays a central role in predicting probability and severity of postoperative infections (12–14,52). However, these risk factors were not uniform among investigators' evaluations.

Clinical Investigation

The overall operative-site infection rate ranges from 6.7% to 44%. Interestingly, patients with preoperative cervical colonization did not have an increase in postoperative complications including duration of hospitalization, operative time, or febrile episodes compared with patients in whom no cervical colonization was demonstrated (53). An overall decrease in significant postoperative infections was reported in retrospective studies among patients undergoing radical hysterectomy (54,55). The benefit, however, was thought to be associated only with reduced local wound infections (56).

Prospective data have not resolved this issue. Numbers of patients in comparative arms have been small, and the data may, therefore, be inadequate for detecting a statistically significant infection rate. Rosenshein et al. noted no significant difference in overall operative-site infection after preoperative prophylaxis (57), an observation shared by Marsden et al (58). In contrast, significantly lower incidences of infection following preoperative antimicrobial prophylaxis were reported by Sevin et al. (59) and Micha et al. (60). Sevin et al. reported that a short course (3 doses) of prophylaxis was as effective as a long course consisting of 12 doses in preventing major infection after radical hysterectomy (61). If separate operative-site data from prospective studies are combined, the overall incidence of pelvic infection and wound infection was significantly reduced by the administration of prophylactic antimicrobials.

A cost-benefit analysis of 3 doses of cefazolin antimicrobial prophylaxis showed a 29% reduction in infectious morbidity following vaginal hysterectomy and an 18% reduction in postoperative infections in patients following abdominal hysterectomy (62).

One patient population that has a significant surgical incision breakdown is that of women undergoing radical vulvectomy. Anecdotal experience indicates the principal pathogens to be *S. aureus* and *S. epidermidis*. The administration of broad-spectrum medications, such as piperacillin or mezlocillin, not unexpectedly, did not significantly reduce the incidence of postoperative wound infection; 8 of 12 women undergoing radical vulvectomy for vulvar carcinoma who were given single-dose piperacillin or mezlocillin developed postoperative infections

(63). We recommend *Staphylococcus* active drug should be considered for women undergoing radical or modified vulvectomy for vulvar carcinoma. Drain sites fall into the same category. The foreign body undoubtedly contributes to the infections; in our opinion, local attention, rather than parenteral or oral antibiotics, is the appropriate preventive approach.

AGENT ADMINISTRATION

Intravenous administration of antibiotics is recommended to achieve high serum and tissue drug concentration and should be given before anesthesia. Antibiotics administered to women undergoing hysterectomy for benign indications by suppository, by spray, and orally, with significant reduction in operative-site infection (64–66). There are no similar data for women undergoing hysterectomy for gynecologic cancer, and these routes of administration are presently not advised.

Timing of Drug Administration

The first dose of an antibiotic should be given intravenously in the operating room. Combination regimens and prolonged administration did not appear to offer superior infection prevention when compared with that provided by a single agent given once. If the interval between the first dose and opening the vagina exceeds 2.5 to 3 hours, a second intravenous dose should be given 15 to 30 minutes before the anticipated vaginal entry. This conclusion is based on data provided by Shapiro et al. (67). This has not been clinically studied, but administration at longer fixed intervals has not enhanced protection at hysterectomy for benign indications. In cancer patients who are expected to undergo a prolonged surgical procedure (>4 hours), the dose may be repeated after 4 to 6 hours.

Recommendations

Intravenous administration of 2 g cefazolin should be given in the operating room. Cefazolin provides activity against gram-negative and gram-positive aerobic and anaerobic bacteria; it is an uncommon therapeutic agent and is comparatively inexpensive—beneficial attributes for a prophylactic antibiotic. A single dose of a prophylactic agent did not result in the selection of a resistant species, as did 3 doses of antibiotics at hysterectomy for benign disease (68). A 1-g dose may suffice, but 2 g was superior to 1 g for vaginal hysterectomy, and three 1-g doses over 16 hours were statistically inferior to a single 2-g dose for cesarean delivery (69). A single dose (1 g) of cefotetan was significantly ($p < 0.05$) superior to 1 g of cefazolin in preventing operative-site infection after elective abdominal hysterectomy for benign diagnoses. The high drug acquisition cost was offset by an overall reduction in hospital costs owing to fewer infections and shorter hospital stays in patients given cefotetan compared with cefazolin (70). Kobamatsu et al. also found superior protection for women undergoing radical hysterectomy when using expanded-spectrum cephalosporins compared with first-generation agents (71). Other alternatives include ampicillin-sulbactam, although there is little evidence to support this practice; similarly, using metronidazole as a single agent may be less effective at preventing infection compared with broad-spectrum cephalosporin agents (72). More prospective data are necessary in patients with gynecologic cancer undergoing surgery.

If the patient is allergic to cephalosporins, or if she has a history of a type I immediate hypersensitivity reaction to a penicillin, and if she is not allergic to a tetracycline, the recommendation is 100 mg doxycycline orally at bedtime the night

before surgery and again the day of surgery about 3 hours before departure for the operating room. This regimen has been evaluated prospectively in Parkland Memorial Hospital, but in a nonrandomized study using very few patients and no control regimen. If the woman is allergic to tetracycline, the recommendation is intravenous administration of 900 mg of clindamycin given preoperatively, as for cefazolin. The new generation of fluoroquinolones such as moxifloxacin may be particularly suited for the gynecologic cancer patient scheduled for pelvic surgery because of its aerobic and anaerobic spectrum of antibacterial activity and extended drug half-life. Prospective, controlled studies are needed.

BOWEL PREPARATION

Unobstructed Bowel

There are approximately 10^{11} bacteria in a gram of feces, making sepsis a major hazard if the colon is opened. It is desirable to reduce the patient's normal colonic microflora to diminish the postoperative infection rate in case it is necessary to perform colonic resection and reanastomosis. Preparation for colonoscopy is a regimen of clear liquids the day before surgery and 3 tablespoons of Fleet Phospho-Soda in one-half cup of cold water at 4:00 PM and 6:00 PM the day before surgery. Patients should be cautioned to drink eight to ten 8-ounce glasses of clear liquids the day before surgery. Additional clear fluid is acceptable. Some surgeons prefer to add a Fleet enema 2 hours before surgery. An alternative mechanical preparation is whole gut irrigation with chilled polyethylene glycol and electrolyte therapy or a similar lavage solution given orally at a rate of approximately 1 L/hour until the rectal effluent is colorless, but for not more than 4 hours. A large cohort multicenter, recently randomized a trial, has placed routine mechanical bowel preparation practice into serious question; in patients who underwent elective colorectal surgery, no difference in anastomotic leak or other septic complications such as fascia dehiscence were noted in the group who had preoperative bowel preparation (73).

In the antimicrobial approach, 1 g each of erythromycin and neomycin is given orally at 1:00 PM, 2:00 PM, and 11:00 PM the day before surgery. This regimen was initially proposed in 1971 by Nichols and Condon (74). An alternative is 1 g each of metronidazole and neomycin at 2:00 PM and at 11:00 PM the day before surgery. There should be no need to add further antimicrobial prophylaxis to 2 g of cefazolin or other agents. Because this may alter hydration status and serum electrolytes, many administer intravenous fluids to patients undergoing mechanical bowel preparation (75).

Obstructed Bowel

There can be no mechanical prophylaxis for preoperative management of the obstructed bowel. Treatment principles include fluid and electrolyte therapy with mechanical decompression of the bowel from above and timed surgical intervention. Women with mechanical intestinal obstruction immediately after surgery may be able to be treated conservatively with decompression only. If necessary, surgery should be performed within 24 hours of the mechanical obstruction; these patients have the lowest mortality rate. A dose of intravenous antibiotic should be given in the operating room before the procedure, with a second dose given in the recovery room, and a third 8 hours later if it is necessary to enter the bowel lumen. The single-agent or combination regimen should provide broad coverage of both gram-positive and gram-negative aerobic and anaerobic bacterial species with a broader spectrum of antibacterial activity

than with cefazolin. Evaluation has produced no evidence for a superior regimen. A single agent usually suffices unless the patient is septic, in which case antibiotic combination is appropriate because therapy, not prophylaxis, is necessary.

CLINICAL SYNDROMES

Peritonitis and Intra-abdominal Abscess

Etiology

Infection in the patient with pelvic cancer most commonly involves the pelvis and abdomen. The potential causes of infection include complications of the primary tumor, surgery, and antineoplastic therapy including radiation and chemotherapy. The tumor can compromise the integrity of the vaginal wall and allow seeding of endogenous vaginal flora into the pelvic and peritoneal cavities. Previous antibiotics, radiation therapy, and the tumor itself may alter the normal genital flora. The tumor can also erode into the bowel and allow entry of fecal material into the peritoneal cavity. Rare cases of several other syndromes arising from untreated pelvic tumor, including spontaneous clostridial gas gangrene and pneumoperitoneum, have been reported (76,77). Peritonitis, with or without abscess formation, may occur postoperatively after hysterectomy or with bowel injury. Radiation therapy to the pelvis can cause radiation enteritis, leading to a chronic diarrheal syndrome, which may develop years after radiation therapy is completed. These patients are also at higher risk for bowel adhesions and subsequent obstruction, and subclinical perforation may present as late insidious intra-abdominal or deep pelvic abscess. Macro and micronutrient malabsorption in patients with chronic diarrheal state may enhance susceptibility for severe systemic infections and extenuate healing process.

Signs and Symptoms

In patients with pelvic cancer, peritonitis may develop at any time, including at initial diagnosis (e.g., tumor infiltration of bowel), immediately postoperatively, or days or weeks after surgery (e.g., tumor infiltration or radiation therapy). The signs are generally dramatic and familiar: abdominal pain, fever, and signs of peritoneal irritation. However, among postoperative patients or patients who have received radiation or corticosteroid therapy, the physical findings may resemble those of a routine postoperative patient, making the diagnosis more difficult. To ensure proper diagnosis, frequent physical examinations, and computed tomography scan should be obtained early in the course of the disease.

Abscess formation can also occur in several settings. In some patients, a subclinical microperforation of the bowel is successfully walled off by the body's immune system, forming a pericolic or intraperitoneal abscess. This has been shown to occur 7 to 10 days after microperforation (78). Fever or mechanical obstruction may be the only presenting sign. Subphrenic, psoas, or liver abscesses may present as a fever of unknown origin and may require a methodical, diligent evaluation for diagnosis. A fistula, usually caused by tumor but also occurring postoperatively, may form between any 2 organ systems, including the bladder, vagina, bowel, or skin. Persistent suppuration despite therapy or the presence of a feculent discharge from the skin, bladder, or vagina may suggest the development of a fistula.

Diagnosis

The diagnosis of peritonitis is usually made on clinical grounds. In patients who have clinical evidence of peritonitis but are

unable to undergo surgery because of bulky tumor, multiple prior surgeries, or general debility, paracentesis with appropriate cultures may be useful in guiding antibiotic therapy. Radiologic investigation is generally required to diagnose an abscess. Regular plain X-ray films of the abdomen are seldom revealing. A sonogram, computed tomographic (CT) scan, or magnetic resonance image (MRI) of the abdomen may show the collection (Figs. 29.7 and 29.8). A gallium scan may also be helpful. In a particularly confusing case in which abnormalities of scans can represent an abscess, metastatic tumor, or postoperative changes, a labeled leukocyte scan may be needed to diagnose the abscess with certainty; these scans are presently seldom used due to inconsistent results and several days to complete the process.

The diagnosis of a fistula requires demonstration of abnormal drainage from one organ system to another. This can be shown by intravenous or intravesical injection of dye for fistulae arising from the bladder, oral or rectal instillation of dye for those arising from the gastrointestinal tract, or a fistulogram for a fistula involving the skin (Fig. 29.9).

In all cases, laboratory abnormalities, including an elevated leukocyte count, reactive thrombocytosis, an elevated erythrocyte sedimentation rate, C-reactive protein and abnormal liver function tests, may suggest the diagnosis and direct the workup. The microbiologic diagnosis in each of these syndromes requires culture for aerobes and anaerobes. Blood cultures are only rarely positive. Some patients may have an unexplained bacteremia of enteric aerobic gram-negative rods or anaerobes. This is probably from a microperforation of the bowel. Any patient with pelvic tumor and enteric gram-negative rods or anaerobic bacteremia should be radiologically evaluated for evidence of perforation.

Therapy

Acute, generalized peritonitis where gastrointestinal perforation is suspected usually requires urgent surgery to irrigate the

peritoneum and repair any perforation. Broad-spectrum antibiotic coverage with agents such as cefoxitin, ticarcillin–clavulanic acid, piperacillin–tazobactam; metronidazole, clindamycin with ampicillin, and an aminoglycoside such as tobramycin or amikacin is generally effective for the polymicrobial infection. Addition of the aminoglycosides is particularly important for patients who have been recently or frequently hospitalized or who have had past courses of antibiotics. These situations predispose the patient to the development of resistant organisms.

Effective treatment of an abscess requires drainage. Percutaneous drainage is adequate in many cases, but laparotomy is occasionally required. Large or persistent abscesses may require placement of a suction drain. Patients with fistulae generally require resection of the involved tissue.

For intra-abdominal infection, intravenous antibiotics directed at the recovered bacteria should continue for at least 10 to 14 days after drainage. Some patients who have been on antibiotics may have evidence of pus but no growth on cultures. In this situation, broad-spectrum antibiotics directed at enteric gram-negative rods and anaerobes should be administered.

FIGURE 29.7. A 58-year-old woman with metastatic ovarian cancer presents with fever, abdominal pain, and elevated white blood cell count. Coronal contrast enhanced CT scan shows multiple loculated fluid collections in the abdomen and pelvis (*) with central displacement of small bowel loops. There is thickening and enhancement of the peritoneal reflection (arrows). These findings could be seen with either peritoneal carcinomatosis or peritonitis. Aspiration of the fluid was compatible with infection and peritonitis.

FIGURE 29.8. A 65-year-old woman with recurrent cervical cancer and fistula tract with the rectum. **A:** Axial CT image performed with enteric contrast shows the large recurrent mass in the midline pelvis (black arrow). There are mottled collections of gas and enteric contrast present within this mass (white arrows) suggesting fistulization with bowel. **B:** Slightly more inferior image demonstrates the contrast-filled rectum (arrow) partially encased by the mass. This was the site of fistulization.

FIGURE 29.9. A 61-year-old woman with recurrent fallopian tube carcinoma and carcinomatosis status post exploratory laparotomy, partial small bowel resection with draining anterior abdominal wall wound. Axial CT scan performed with enteric and IV contrast demonstrates a loop of small bowel adherent to the anterior abdominal wall with enteric contrast-containing tract within the abdominal wall soft tissues (black arrows). There is a contrast-containing collection in the overlying subcutaneous soft tissues. These findings are compatible with enterocutaneous fistula. Additional intraperitoneal abscess is noted (white arrow).

Laboratory parameters such as leukocyte counts should be followed to determine the exact duration.

Patients who are inoperable can be treated with chronic suppressive therapy, intravenously or orally. Oral agents such as amoxicillin-clavulanic acid (875 mg bid) or clindamycin (450 mg q 6 to 8 hours) may be effective. Ciprofloxacin, moxifloxacin, or levofloxacin alone should not be used in this situation because they provide limited coverage for *Enterococcus* species.

Patients with infections due to vancomycin-resistant enterococci and/or vancomycin-tolerant (79) *Streptococcus* or *Staphylococcus* species may be treated with daptomycin (6 mg/kg daily) or linezolid (600 mg twice daily), usually in combination with drugs with gram-negative and anaerobic activity. Tigecycline may also be used as an alternative; it has broad spectrum antimicrobial activity including promising *in vitro* results against multidrug-resistant bacteria such as extended-spectrum beta-lactamase positive *E. coli*, multidrug-resistant *Acinetobacter*, *S. maltophilia*, carbapenemases producing *K. pneumoniae*, vancomycin-resistant enterococci, and multidrug-resistant *S. aureus*. There is limited clinical data for its use in patients with gynecologic malignancy, and due to poor activity against *Pseudomonas* species it should be used cautiously in neutropenic patients and those with prior invasive *Pseudomonas* infection or known bacterial colonization. Furthermore, emergence of drug-resistant bacteria or selection of less-susceptible organisms remains a concern for widespread use of drugs with broad-spectrum antimicrobial coverage. Similarly, antipseudomonal carbapenems such as imipenem-cilastatin and meropenem should also be reserved for seriously ill patients with polymicrobial infection, as emergence and spread of multidrug-resistant gram-negative bacteria are increasing in immunosuppressed cancer patients (80). Ertapenem, a carbapenem without antipseudomonal activity, was as effective as piperacillin-tazobactam for the treatment of acute pelvic infection (81), and can be administered as a single daily dose, albeit due to lack of enterococcal coverage it is important to select patients carefully.

Urinary Tract Infection

Etiology

Many clinical situations predispose a patient to urinary tract infection. Urinary tract infection continues to be the leading cause of infectious morbidity in this population. One study showed that half of the patients with pelvic cancer admitted to the hospital because of infection had a urinary tract infection; *E. coli* was the most common organism isolated (82). Another report found that the frequency of urinary tract infections is increased as much as threefold in patients undergoing pelvic irradiation (20–22). Many patients who undergo pelvic surgery require prolonged bladder catheterization, usually with a Foley catheter. These patients may develop well-recognized infectious complications of chronic bladder catheterization, the most common of which is recurrent infection. In addition, tumor can cause urinary obstruction and subsequent infection. The role of antiseptic or antibiotic-impregnated urinary catheters has not yet been defined.

Signs and Symptoms

Some patients with gynecologic malignancy and urinary tract infection have the familiar clinical picture of dysuria, fever, flank or suprapubic tenderness, elevated leukocyte count, and abnormal urinalysis. In many others, these signs and symptoms are obscured by the rest of the clinical picture. For instance, a postoperative patient may be expected to have abdominal tenderness, an elevated leukocyte count, and fever. The physician should consider the entire clinical setting before embarking on a course of therapy.

Diagnosis

Diagnosis is generally made on the basis of a urine culture, from a “clean catch” or through a catheter, but the initial urinalysis is extremely helpful. Pyuria is expected in any nongranulocytopenic patient with a urinary tract infection. Gram stain of urinary sediment can direct antibiotic therapy in advance of the culture results. A common problem confronting the physician is when patients, especially those with indwelling catheters or nephrostomy tubes, have positive urine cultures but do not appear to be ill. Differentiating colonization from invasive infection is frequently not simple and requires clinical judgment. Any patient who is not severely neutropenic should also have pyuria along with positive urine cultures. The absence of pyuria in a patient with a positive urine culture suggests the likelihood of simple asymptomatic bacteriuria. From a practical standpoint, in a clinically stable patient, it is reasonable to withhold antibiotics pending repeated urinalysis and urine culture. If an organism persists, therapy may be considered.

Therapy

Therapy should be based on the sensitivity pattern of the recovered organism, and intravenous antibiotics are reserved for patients with drug-resistant bacteria and those with systemic infection, ascending infection, or pyelonephritis. Optimum duration of therapy in a patient with a urethral stent or a permanent indwelling catheter is often difficult to determine. It is virtually impossible to eradicate an infection in the presence of a foreign body, and removal of the foreign object is highly desirable, however, removal is not always feasible. A patient with a urinary tract infection and a foreign body in the urinary collecting system should be considered for chronic suppressive therapy if she has recurrent infection. In general, among patients with gram-negative rods, chronic suppressive therapy may include ampicillin, trimethoprim-sulfamethoxazole, doxycycline, or

an oral fluoroquinolone such as ciprofloxacin. Patients with a chronic enterococcal infection may benefit from chronic suppressive therapy with amoxicillin–clavulanic acid (Augmentin) or amoxicillin alone or doxycycline.

In patients with pyuria and fever in whom a urinary tract infection is suspected, empiric antibiotic therapy should be given pending urine culture results. Gram stain of urinary sediment may be helpful in directing treatment. However, for those cases in which Gram stain is not helpful, broad-spectrum coverage should be given. For a patient who has had frequent or prolonged hospitalizations, effective coverage of potentially resistant gram-negative rods dictates that 2 drugs be given, preferably a beta-lactam and an aminoglycoside. Cefazolin (1 to 2 g IV, q 8 hours) and gentamicin (4 to 5 mg/kg per day IV in 3 divided doses) is a good empiric combination for many patients. For more debilitated patients or those with prolonged hospitalizations and frequent past courses of antibiotics, advanced generation cephalosporin, such as ceftazidime (1 to 2 g IV, q 8 hours) or ceftepime (1 gram IV, q 8 hours) should be substituted for cefazolin. After culture results are known, antibiotics can be adjusted and the spectrum narrowed. For any gynecologic cancer patient with an unexplained predisposition to recurrent urinary tract infection, a full investigation should be undertaken to exclude obstruction from tumor as the cause.

Wound Infections

There are important variables that influence the development of wound infection after surgery. These include hospital flora, patient microflora, operative technique and variables, patient nutritional status, and competency of innate and adaptive immune function. Women being treated for reproductive tract cancer may be at risk because of specific problems with immunocompetency, possible prior chemotherapy or radiotherapy, poor nutritional status, hypoproteinemia, economically disadvantaged, or advanced cancer-associated catabolic state. Additional risk factors for incisional infection include obesity, inadequately controlled diabetes, and systemic corticosteroid use. Surgical variables include operative procedures in excess of 4 hours, breaks in surgical technique, capacious incision at the operative site, excessive cautery, passive drains, shaving of the area in which the incision is made immediately before surgery, and placement and types of sutures. Infections may range from a mild cellulitis to a devastating fasciitis, deep infection with myonecrosis, and mixed anaerobic–aerobic synergistic abdominopelvic gangrene (83).

Cellulitis

Etiology

Cellulitis is a relatively frequent occurrence. The presence of a foreign body in a wound is an unavoidable risk factor in many cases, but this variable should be removed or reduced as much as possible. Devitalized tissue, especially fat, can also act as a foreign body. Excess cautery causes thermal injury; the charred tissue may act as a foreign body. The presence of significant amounts of devitalized tissue usually produces a wound defect. A mechanical wound retractor can cause fat necrosis, and there appears to be only minimal ability to resorb these areas during wound healing. These areas should be carefully identified and excised before closing the wound. If drains are used, they should be closed, and drains should be vacuumed. Drains should not exit through the wound but rather through an adjacent puncture site, and they should be removed as early as possible. *S. aureus* is recovered from 50% or more of wound infections. If the operative procedure involves transection of the vagina, the

infections may harbor other species of normal flora of the lower reproductive tract, such as gram-positive and gram-negative anaerobes and *Enterobacteriaceae*. Cellulitis of the leg occurs with increased frequency in patients after vulvectomy (84). The affected leg is not always edematous. Group B beta-hemolytic streptococci are frequently recovered. Prophylactic therapy with oral penicillin may reduce recurrences in some patients (84). Increased prevalence of penicillinases among clinical streptococcal isolates cautions against penicillin preparation without beta-lactamase inhibitor.

Signs and Symptoms

Cellulitis is almost uniformly associated with pain and erythema in the incisional margins, with an increase in local skin and tissue temperature, and many times with fever. Incisions are usually tender at examination. Incisional cellulitis may not become evident until the fourth postoperative day or later.

Diagnosis

The infected surgical incision should be explored. This can frequently be performed at the bedside. Opposing skin edges in such incisions are usually separated without difficulty and may expose underlying purulent material, seromas, hematomas, or any combination of these. The wound should be explored thoroughly, and if the wound shows unusual features, aerobic and anaerobic cultures should be obtained. Foreign bodies such as sutures or drains should be removed, and obviously necrotic areas should adequately debrided. It is important to document deep fascial integrity. If this cannot be done at the bedside, it should be performed in the operating room.

Therapy

The wound should be packed open with fine-mesh gauze approximated to the incisional margins and changed with each dressing change. The dressing is changed 2 to 4 times daily; avoiding harsh chemical and repeat mechanical debridement in the absence of necrotic tissue. Commonly used solutions are hydrogen peroxide, acetic acid, and Dakin's solution (0.25% sodium hypochlorite). In general, these debriding solutions should be removed from the wound with sterile normal saline before packing because they may impede healing. Except in unusual instances, it is unnecessary to administer parenteral antimicrobials. These incisions may be left open to heal by secondary intent, or they may be closed before discharge from the hospital after the margins exhibit healthy viable granulation tissue. The optimal time for secondary closure is about the fourth day after institution of wound therapy. Studies have shown that normal wound healing occurs as long as the hematocrit exceeds 17%, but then a lower level will impede healing (85).

Necrotizing Fasciitis

Necrotizing fasciitis is a potentially life-threatening infection of the soft tissues above deep fascia that can involve the abdominal wall or vulva with extension to the proximal thighs and buttocks (85). There are several descriptive names for this infection, such as beta-hemolytic streptococcal gangrene, hospital gangrene, gram-negative anaerobic cutaneous gangrene, non-clostridial gas gangrene, gangrenous erysipelas, or synergistic necrotizing cellulitis, but the name used by most is that coined by Wilson in 1952, that is, necrotizing fasciitis (86). This significant infection has been reported in patients with endometrial cancer following irradiation and hysterectomy (87–89). It has also been found in endopelvic fascia, in a suprapubic catheter

site during chemotherapy, in the vulva in diabetes, and after diagnostic laparoscopy (90–95).

Etiology

Bacteria recovered from necrotizing fasciitis infected sites include anaerobes, particularly *Peptostreptococcus*, *Prevotella*, and *Bacteroides* species, as well as *E. faecalis*, *S. aureus*, and *Enterobacteriaceae*. These bacteria produce large quantities of proteolytic and other enzymes and toxins that allow rapid spread to contiguous tissues. Superficial vessels are occluded, depriving the affected areas of oxygen, other nutrients, and antibiotics. This deprivation interferes with bacterial eradication. Patients at particularly high risk of developing this infection include women older than 50 years of age and those with arteriosclerotic heart disease, diabetes, or other chronic diseases.

Signs and Symptoms

Early in the course of necrotizing fasciitis, the signs and symptoms are those of any wound cellulitis. Because there is no response to the usual methods of therapy, antibiotic therapy will frequently be initiated. The infection, however, seems to smolder initially, then rapidly progresses to involve the wound and to produce clinical sepsis. Mortality rates for this infection have been as high as 76%. The degree of disease evident on the skin is only a small fraction of the total amount of tissue that is involved because the skin is not the primary area of infection. Hallmarks of this infection include the presence of severe pain in contrast to scant physical findings, edema and superficial crepitance may be present. The skin overlying the affected area becomes blue or brown as the disease progresses, and there may be formation of bullae. Edema progresses, and there may be seepage of grayish fluid from the skin and does not bleed if cut. Lack of familiarity with this infection and failure to recognize its signs may delay diagnosis. Even when recognized and treated early, there is a high mortality rate.

Diagnosis

Diagnostic criteria as first outlined by Fisher et al. (96) include the following:

1. Extensive necrosis of the superficial fascia with widespread undermining of surrounding tissue
2. A moderate to severe systemic toxic reaction
3. Absence of muscle involvement
4. Failure to demonstrate *Clostridium* species in the wound or blood cultures
5. Absence of major vascular occlusion
6. Histologic demonstration of intense leukocytic infiltration, focal necrosis of the superficial fascia and surrounding tissues, and microvascular thrombosis

Early diagnosis followed as soon as possible by appropriate treatment produces the highest cure rate. Radiologic evaluation, particularly with MRI, may confirm the diagnosis rapidly, and should be ordered whenever the disease is suspected. The average interval between diagnosis and initiation of treatment is approximately 5 days. If the interval is 4 days or less, survival rates are high, but an interval of 7 days or more is more likely to result in patient death because even intense antimicrobial therapy is rarely successful at this late stage.

Therapy

Although the administration of broad-spectrum antimicrobials is important, wide and often disfiguring surgical debridement is the treatment required for preservation of life. The excision must extend to areas that bleed. Adjunctive therapy with whirlpool

baths and perhaps hyperbaric oxygen may be considered early in the course of the disease.

Clostridial Myonecrosis

Clostridial myonecrosis (gas gangrene) was described by Altmeier (97). It is an infection that occurs in muscle and adjacent tissues beneath the deep fascia and is seen most commonly after trauma. However, it can be seen after intra-abdominal surgery or surgery in an area that has been contaminated by feces. Mortality rates are about 25%, and poor-prognosis factors are leukopenia, advanced age, renal failure, and intravascular hemolysis.

Etiology

Clostridial myonecrosis is caused by *C. perfringens* (80% to 95%), *C. novyi* (10% to 40%), or *C. septicum* (5% to 20%). It is usually seen in association with gastrointestinal mucosal ulceration or perforation because *Clostridium* species are normal inhabitants of the gastrointestinal tract. *C. perfringens* may be isolated from as many as 20% of the women with upper genital tract infections not involving sexually transmitted diseases. The mere presence of *C. perfringens* in a wound does not mean that the patient will develop gas gangrene; it develops in only 1% to 2% of wounds in which that species can be isolated.

Signs and Symptoms

Early signs and symptoms of clostridial myonecrosis are tense edema in tissue that is extremely tender and pain that rapidly intensifies. If an incision is open, it is not uncommon to see a swollen, herniated muscle. There is frequently a serosanguinous, dirty discharge that has many gram-positive or gram-variable rods but few leukocytes. There may also be gas bubbles, and the secretions have a particularly sweet, offensive odor. The surrounding tissue frequently has crepitus. The skin becomes red to green-purple and then turns yellow before becoming a characteristic bronze color. The usual incubation period is about 2 to 3 days, but it can be as short as 6 hours. With progression of the infection, the patient becomes obviously ill, pale, and sweaty, with increased pulse rate and decreased blood pressure. Temperature is usually elevated, but hypothermia and shock may occur early in the course of the illness.

Diagnosis

A positive wound culture may accompany the characteristic signs and symptoms of clostridial myonecrosis. X-ray films of the affected area frequently show gas deep in the tissues. Blood cultures grow clostridia in approximately 15% of the cases. It is common to find a decrease in hemoglobin and an increase in circulating leukocytes. Involved muscle is pale and edematous, with loss of elasticity, and it does not bleed or contract with stimulation. Histologic findings demonstrate coagulation necrosis of muscle fibers.

Therapy

Clostridial myonecrosis is another infection that requires prompt and extensive debridement in the operating room. Cultures must be performed, and because clostridia may develop plasmid-mediated antibiotic resistance, repeated cultures with sensitivity testing may be required if a patient is slow to respond. In addition to wide debridement, the treatment of choice is penicillin G at a dose of 1 to 2 million units every 2 to 3 hours. Gram stain also may indicate the presence of gram-negative bacteria, in which case, coverage should be provided for those bacteria

as well. Chloramphenicol is as effective against *Clostridium* species as it is against many gram-negative species, although seldom used due to potentially life-threatening drug toxicity. Metronidazole, imipenem, or clindamycin, all of which having good *in vitro* activity against *C. perfringens*, may be considered. Other antibiotics with good *in vitro* activity include tetracycline, erythromycin, and rifampin. Hyperbaric oxygen may be adjunctive, but its efficacy is uncertain.

Intraperitoneal Catheter Infections

Etiology

Delivery of chemotherapeutic agents through an intraperitoneal catheter has enabled physicians to deliver high concentrations of drug locally while decreasing systemic side effects (42,98). However, intraperitoneal catheters can become infected at the exit site, along the catheter tunnel, or secondary peritonitis may occur in rare cases. *S. epidermidis* is the most common organism followed by *S. aureus* and *Streptococcus* species. Gram-negative bacilli and anaerobes, presumably from the bowel, are also found, especially in patients with polymicrobial infections. Patients who have been treated for bacterial peritonitis in the past may develop peritonitis due to *Candida* species.

Signs and Symptoms

With exit-site or tunnel infections, patients report discomfort at the site. Patients with peritonitis may complain of diffuse abdominal pain, with or without a change in bowel pattern. Fever may be absent in peritonitis, making the diagnosis more difficult because many patients with pelvic tumor have abdominal pain. On examination, patients with exit-site or tunnel infections have redness and sometimes have discharge where the catheter has been inserted. Patients with peritonitis have tenderness and frequently have abdominal rebound.

Diagnosis

Diagnosis of exit-site and tunnel infections is made clinically, with support from a Gram stain and culture of any discharge. Patients with suspected peritonitis should have withdrawal of peritoneal fluid for cell count and microbiologic evaluation. A rough guideline, derived from experience among patients receiving continuous ambulatory peritoneal dialysis, is that any leukocyte count in peritoneal fluid >100 cells/mm³ suggests infection. Gram stain and culture should reveal the specific organism. Chemical peritonitis after instillation of chemotherapy can mimic infectious peritonitis. Peritoneal fluid cultures are often not helpful in distinguishing between infectious versus chemical peritonitis, especially in infections due to a fastidious organism. Use of biomarkers such as C-reactive protein or procalcitonin remains uncertain.

Therapy

For patients with peritonitis, systemic therapy is advised according to the recovered organisms. Treatment should be continued for 10 days or longer, with serial peritoneal fluid cell counts guiding therapy. The peritoneum provides a large absorptive surface, and antibiotics delivered intraperitoneally readily enter the intravascular space; however, we suggest that intraperitoneal antibiotic therapy should be reserved for patients with serious, treatment-refractory infection. Treatment of fungal peritonitis is a unique problem. Amphotericin B can cause adhesions if delivered intraperitoneally. Echinocandins such as micafungin and caspofungin appear to be the treatment of choice for patients with intra-abdominal and peritoneal candidiasis (99). Fluconazole, which can be administered orally or intravenously, was shown in

one study of patients receiving continuous ambulatory peritoneal dialysis to effectively treat *C. albicans* peritonitis and should be avoided in patients with *Candida glabrata* and *Candida krusei* infection (100). Fluconazole may be used for long-term therapy in patients with *Candida* peritonitis who have responded to initial aggressive therapy with micafungin (100 mg IV daily) or caspofungin (70 mg $\times$ 1 IV followed by 50 mg IV daily).

Septic Pelvic Thrombophlebitis

Septic pelvic thrombophlebitis, also known as suppurative pelvic thrombophlebitis, is a disorder that has been diagnosed most frequently after antimicrobial therapy for pelvic infection after cesarean section or septic abortion, but it can be seen as a complication of infection after any type of pelvic surgery. The mortality rate observed in 1917 was 52% after surgical therapy (101). Fortunately, this complication of pelvic infection is now very rare. The use of antimicrobial prophylaxis and the enhanced antibacterial activity of current therapeutic regimens are presumed to be paramount in the disappearance of this potentially lethal infection.

Etiology

Septic pelvic thrombophlebitis is clot formation in the pelvic veins as a result of infection. It can be seen after hysterectomy, other pelvic operative procedures including brachytherapy, and in association with pelvic trauma or perirectal abscess. Classically, there is relative venous stasis before phlebitis that develops adjacent to pelvic infection. The intimal lining of the veins is invaded by bacteria, including *Enterobacteriaceae*, especially *E. coli*, aerobic and anaerobic streptococci, and *Bacteroides*. The veins involved may be the ovarian, hypogastric, or uterine, with essentially equal involvement in the right and left sides. If common iliac veins are involved, clot formation is more frequently seen on the left for unknown reasons. Infected clot may embolize to the lungs, kidneys, liver, brain, and spleen.

Signs and Symptoms

A clinical diagnosis may not be readily evident. Presentation is essentially that of a fever of unknown cause, and the physician must rule out infections such as pyelonephritis, pneumonia, and pelvic or abdominal abscess. The most frequent presentation currently seen is persistence of fever associated with tachycardia after clinical response to antimicrobial therapy for a pelvic infection. Physical examination is normal in most instances, but it may be possible to palpate tender cords in the vaginal fornices. In patients with bacteremia and septic emboli, chills are observed in as many as 67% of the patients, pyrexia may be elevated to 41°C, and the variations in temperature may be quite hectic. Dyspnea, tachypnea, pleuritic pain, cough, hemoptysis, restlessness, anxiety, and perhaps angina may all be seen with septic embolization.

Diagnosis

Compatible clinical presentation and CT or MRI scan are used for diagnosis (102). Criteria for diagnosis of venous thrombosis using CT studies include enlargement of the involved vein(s), sharply defined vessel walls enhanced by contrast media, and a low-density intraluminal mass (103). Diagnosis using MRI is based on intense intraluminal signals from clot in involved veins and a lack of signal with normal blood flow in uninvolved vessels; no contrast agent is needed. Blood culture should be performed if there is suspicion of septicemia. Tests for blood gases, a chest radiograph, and IV contrast enhanced chest CT scan or in patients with contraindication to IV contrast use, a

ventilation-perfusion scan may be performed to assess pulmonary embolization. A gallium scintiscan may be necessary to identify very small septic embolic foci in the lungs.

Therapy

Early treatment of venous thrombosis was surgical (101). The first to advocate the use of anticoagulants in addition to antibiotics were Schulman and Zatuchni (104). In some cases, antibiotics alone may be adequate and can be used in patients in whom anticoagulation can be detrimental (105). In the largest published study of heparin therapy, the mean time to become afebrile was 2.5 days, and the average duration of heparin therapy was 8 days (106,107). It is unnecessary to initiate warfarin sodium (Coumadin) therapy in patients without evidence of emboli. Thromboembolism during or after treatment with heparin has not been reported. Antibiotic therapy must be continued. If there is significant improvement in the pulse rate and temperature pattern within 12 to 48 hours after addition of heparin, reassessment is mandatory. Treatment with low-molecular-weight heparin has not been studied or standardized for this condition (108). Heparin therapy is not without complications. Between 2% and 5% of patients may have an allergic reaction; bleeding occurs in 7% to 10% of patients; and the most devastating effect is the development of the “white clot syndrome” (109). This occurs in <1% of patients, but it may be associated with major limb amputation in 20% of those suffering from it, and death has been reported in nearly half of these patients. This phenomenon is a paradoxical arterial platelet aggregation associated with thrombocytopenia, and it should be suspected in patients with decreasing platelet counts or an increasing requirement of heparin to maintain adequate anticoagulation. The only current indications for surgical intervention are embolization during heparin therapy or lack of response. The usual intervention is placement of a vena cava filter, which is a procedure usually performed by an interventional radiologist.

Neutropenia and Fever

Etiology

Patients with severe neutropenia are at particularly high risk for severe morbidity and mortality unless empiric intravenous antibiotic therapy is instituted at the first evidence of fever or clinical worsening. Most commonly, the febrile neutropenic patient does not have an obvious source of fever. Even in those with bacteremia, the source is rarely clinically evident. Bacteria often enter the bloodstream through the gastrointestinal tract because of the small chemotherapy-induced disruption of the intestinal mucosa and the accompanying neutropenia and thrombocytopenia. Neutropenic patients may also develop a clinically diagnosed group of infections, including pneumonia and cellulitis. Neutropenic patients with these clinically diagnosed infections may progress very rapidly, may have exceedingly subtle clinical signs and symptoms, and always require early, aggressive therapy of their infections to achieve a response.

Signs and Symptoms

Fever is often the only complaint of patients with neutropenia and bacteremia. Patients receiving chemotherapy should be instructed to take their own temperature at home twice a day (more frequently if a subjective feeling of fever develops) and to contact their treating physician for temperatures above 38.0°C, or 100.4°F.

Diagnosis

Diagnosis is made by blood culture. Of all febrile, neutropenic patients from whom blood cultures are obtained, only 10%

to 20% have an organism isolated. The others probably have enough organisms to cause fever and systemic illness, but an insufficient burden of microorganisms to be cultivated using current standard culture-based techniques. Coagulase-negative *Staphylococcus*, *S. aureus*, streptococci, *E. coli*, *Klebsiella* species, and *Pseudomonas* species are frequently isolated bacteria (110). In a recent report of 2,142 patients with febrile neutropenia, 499 (23%) patients developed bacteremia due to gram-positive bacteria (57%), gram-negative bacteria (34%) and polymicrobial infection was seen in 10% (111). Mortality rates were lowest (5%) in patients with gram-positive infection followed by 18% with gram-negative bacteremia, and they were 13% in patients in whom polymicrobial bloodstream infection was diagnosed (111). Polymicrobial infections are often underreported, and neutropenic patients with intestinal and genitourinary tract mucosal damage have a higher risk of systemic infection due to multiple microorganisms (7).

Therapy

The Infectious Disease Society of America (IDSA) updates guidelines for management of the patients with fever and neutropenia. Full consideration of this complex topic is beyond the scope of this chapter (112). In general, a febrile neutropenic patient should receive antibiotics with activity against *P. aeruginosa* pending results of blood cultures. Numerous regimens are effective, and their use should be determined according to sensitivity patterns for *P. aeruginosa* at a given hospital. In general, good results have been achieved with a beta-lactam antibiotic plus beta-lactamase inhibitor such as ticarcillin-clavulanic acid, piperacillin-tazobactam, or a third-generation cephalosporin such as ceftazidime or cefepime, or a carbapenem such as imipenem or meropenem with or without an aminoglycoside. Monitoring peak and trough levels of aminoglycosides is recommended to maintain drug levels in optimum therapeutic range and to mitigate drug-induced ototoxicity and nephrotoxicity. The choice of the specific aminoglycoside (e.g., tobramycin, amikacin) is dictated by the sensitivity patterns in a given hospital. Once-daily dosing of aminoglycosides is not recommended for the neutropenic patient but can be given in other settings. The length of therapy for neutropenic patients is determined by many factors and must be individualized. Patients with prolonged neutropenia and fever should be followed by an infectious disease specialist.

Fungal Infections

Etiology

Patients with pelvic cancer may be at risk for the development of fungal infections, particularly those caused by *Candida* species, including *C. albicans*, *C. tropicalis*, *C. parapsilosis*, and *C. glabrata* (113). Infection may include fungemia, pelvic abscess, or infected urinary stents in patients with extensive pelvic disease and urinary outflow obstruction. Risk factors for the development of invasive candidiasis include prolonged courses (7 to 10 days) of intravenous broad-spectrum antibiotics; an intravenous catheter, particularly a central venous catheter; major abdominal surgery; treatment-induced severe neutropenia for longer than a week, and immunosuppressive therapy, especially with corticosteroids. Patient with enteric or colonic fistula or bowel perforation have an increased risk for tissue invasive candidiasis (114).

Signs and Symptoms

Patients with the appropriate risk factors who have unexplained fevers may be fungemic. Other than fevers, which can include rigors and hypotension and closely resemble bacteremia, there may be no other symptoms. Blood cultures are positive in only

50% of the patients with autopsy-proven disseminated candidiasis. Any blood culture positive for yeast should be considered to be significant. A full evaluation for a hidden source should be completed, including a thorough reevaluation with history and physical examination, and appropriate laboratory tests that include repeat blood cultures. It is imperative to perform an expert ophthalmoscopic examination for possible *Candida* vitritis, retinitis/retinal abscesses or endophthalmitis should be performed in all patients with presumed, probable or definite fungemia, since this complication may occur in up to 5% to 15% of patients with fungemia (115).

Presence of multiple body-site *Candida* species colonization proportionally increases the risk for invasive candidiasis including fungemia and acute disseminated candidiasis (116). *Candida* species may cause urinary tract infection in a patient with such indwelling devices as a Foley catheter, internal stents, or percutaneous nephrostomies. Rarely a “fungus ball,” consisting of a matted mass of yeast, may cause urinary tract obstruction. *Candida* species invasive lung disease is exceedingly rare and may occasionally be seen in critically ill and in high-risk patients at intensive care unit or patients with refractory relapsed acute leukemia and prolonged severe neutropenia. Thus, recovery of any yeast from a respiratory specimen should be considered to be most likely due to oropharyngeal contamination of lower respiratory tract culture. Unlike patients with leukemia and recipients of allogeneic hematopoietic stem cell transplantation, in patients with gynecologic malignancy invasive mold disease is exceedingly rare. Identification of filamentous fungi, such as *Aspergillus*, should be approached with caution and mold-active drug therapy reserved for highly immunosuppressed patients with clinical and radiographic features suggestive of invasive aspergillosis in this patient population (117).

Diagnosis

The diagnosis of a fungal infection is often difficult. The physician must differentiate between invasive disease, which must be treated, and colonization, which does not require systemic antifungal therapy. The recovery of fungi from a urine, sputum, or wound culture does not necessarily mean that the fungus is pathogenic, and clinical judgment must be used to determine if a patient requires therapy. In general, cultures from sterile sites (e.g., blood, cerebrospinal fluid, pleural or peritoneal fluid) should be considered to represent invasive infection until a full evaluation is done. Also, *Candida* recovered from the initial specimen of drainage from an obstructed biliary or urinary tract should be considered to be potentially associated with invasive fungal disease.

With most specimens, however, the distinction between colonization and infection is not so simple. For urine, the presence or absence of pyuria is the simplest and most reliable means of differentiation. Those without pyuria are very likely only colonized and need no therapy. In such patients, a repeat urinalysis and culture may clarify the situation. Recently approved fungal antigen assays including serum beta D glucan and galactomannan have provided much needed diagnostic sensitive and specificity in select group of patients with high risk for invasive fungal disease (118).

Therapy

Treatment options for invasive candidiasis have expanded in recent years. Amphotericin B has the longest record for treatment of invasive fungal infections (113). The optimal duration of therapy for candidemia is not well-defined and should be determined by individual responses. However, a 7- to 14-day course of therapy is probably adequate for most episodes (113).

Since the introduction of fluconazole in 1990, the option for invasive candidiasis, severe drug toxicity associated with amphotericin B is observed less and less (113,119). Echinocandins such as caspofungin (70-mg load and then 50 daily IV) showed

comparable response in patients with invasive candidiasis versus patients randomized to receive amphotericin B (99). In a large prospective trial, comparing first 2 available echinocandins showed 75% efficacy for micafungin compared with 70% in patients treated with caspofungin at the end of antifungal therapy; there were also nonsignificant higher responses among patients with *Candida* peritonitis (67% vs. 40%) and deep tissue abscesses (100% vs. 67%) in micafungin group versus caspofungin, respectively (120). These new class of drugs offer comparable effectiveness but have fewer side effects than the amphotericin B products.

Patients who have *Candida* species consistently cultured from urine but no evidence of systemic fungal infection may benefit from bladder irrigation with amphotericin B, which reduces or eradicates bladder yeast colonization, and may prevent invasive fungal infection. Fluconazole is increasingly being given for this indication and appears to be effective.

Pneumonia

Etiology

Postoperative pneumonia remains a common cause of fever in any surgical patient, including those with gynecologic cancer. Infection may occur from aspiration during intubation or extubation or from hypoventilation due to “splinting” in patients with severe postoperative pain. Postobstructive pneumonia may occur in patients with tumor metastatic to the lungs. In addition, pneumonia may occur in patients with chemotherapy-induced neutropenia.

Signs and Symptoms

The familiar signs and symptoms of pneumonia are cough, fever, chest discomfort, and dyspnea and evidence of pulmonary consolidation on lung examination.

Diagnosis

The diagnosis is usually suggested by the clinical situation and by the findings on physical examination. These are further supported by chest radiographs and sputum examination and culture. Chest radiography may show consolidation (Fig. 29.7). Gram-negative organisms predominate in the mouth flora of hospitalized patients, so an aspiration pneumonia occurring in a hospitalized patient is typically due to gram-negative rods. Although thought by many to be a substantial contributor, anaerobes seldom isolated in hospitalized patients with aspiration pneumonia.

Therapy

Empiric, rather than pathogen-directed, coverage of patient following major surgical procedure with clinical pneumonia is usually necessary and varies according to the setting (121). For a patient who has been hospitalized less than 3 days and has had no other recent hospitalizations or recent courses of oral or intravenous antibiotics, single-drug therapy with levofloxacin or moxifloxacin is adequate (121). For the patient who has been hospitalized for a longer period or who has recently received broad-spectrum antibiotics (increasing the likelihood of infection due to multi-drug resistant organisms), *P. aeruginosa* should be covered by the addition of an aminoglycoside such as gentamicin or tobramycin (3 to 5 mg/kg per day in 3 divided doses), and a beta-lactam should be selected to cover the usual isolates in that hospital. *S. maltophilia* is now increasingly seen in cancer patients without traditional risk factors such as severe neutropenia, prolonged stay in critical care units, or mechanical ventilation (122). Treatment includes high-dose trimethoprim-sulfamethoxazole (15 mg/kg in 3 to 4 divided doses) in combination with a second drug to which the bacteria are susceptible

(17). Patients with *S. aureus* pulmonary infection may present with rapid clinical deterioration and necrotizing pneumonia due to MRSA is often seen as complication following a recent influenza virus like illness; the postviral bacterial infections are especially serious superinfections and require urgent, appropriate antibiotic therapy. Vancomycin (1 g twice daily) or linezolid (600 mg every 12 hours) may be given in patients with lobar or multifocal pneumonia and history of recent influenza-like illness. Therapy for patients with pneumonia should extend up to 10 to 14 days depending on (a) clinical response, (b) concurrent bacteremia, (c) presence of empyema or complicated parapneumonic effusion, or (d) secondary hematogenous foci of infection dissemination. Various professional societies have codified recommendations for pneumonia management (123).

GASTROENTEROLOGIC SOURCES OF INFECTION

Diarrhea Associated with Antibiotics or Chemotherapy

Etiology

Diarrhea is a common finding in patients undergoing treatment of gynecologic malignancy. In a study of 351 hospitalized women with gynecologic cancer in 1980s, 12% developed diarrhea during the course of their hospital stay (Fig. 29.11); 10% had diarrhea due to *Clostridium difficile* (124). In cancer patients, *C. difficile* associated diarrhea (CDAD) is most commonly as a result following exposure to broad-spectrum antibiotics or in some cases chemotherapy alone (124,125).

Signs and Symptoms

Antibiotic-associated diarrhea can occur at any time during an antibiotic course and for at least a month after discontinuation. Patients typically develop abdominal pain, fever, and frequent watery diarrhea defined as ≥ 3 unformed bowel movements in 24 hours lasting for ≥ 2 days; however, CDAD may sometimes cause abdominal pain and fever without diarrhea.

Diagnosis

Any patient with antibiotic-, radiation-, or chemotherapy-associated diarrhea should have a full evaluation of stool, including routine cultures and antitoxin immunoassays or nucleic acid amplification tests (126). CT scans may be helpful in localizing areas of bowel inflammation, especially in the prior radiation field (Fig. 29.10). In patients with a highly suspicious clinical and radiographic presentation but no evidence of *C. difficile* toxin in stool, sigmoidoscopy or colonoscopy may reveal intense mucosal ulceration and inflammation, and the pathognomonic pseudomembranes are observed in small number of cases with advanced disease. CT scan may not be able to differentiate between chemotherapy associated versus diffuse bowel edema in patients with CDAD (Figs. 29.11 and 29.12). One study has suggested that evaluation of stool for *C. difficile* toxin is the only cost-effective test (124). A markedly elevated white blood cell count may also be a clue to diagnosis (127). In a recent retrospective study from a tertiary care cancer center, PCR increased the yield of *C. difficile* cases by twofold compared to that of the standard cytotoxic assay (128). Currently, in most secondary and tertiary care medical centers, nucleic acid amplification assay have largely replaced the less sensitive immunoassays.

Therapy

Oral therapy with metronidazole (250 mg to 500 mg 4 times daily for 2 to 4 weeks) is adequate to treat most cases of

FIGURE 29.10. A 56-year-old woman with cervical cancer being treated with radiation therapy presented with pelvic pain. Axial CT performed with enteric and IV contrast demonstrates mural thickening of small bowel loop in the lower pelvis (arrow) secondary to radiation enteritis.

FIGURE 29.11. A 57-year-old woman with recurrent ovarian cancer treated with chemotherapy. Coronal CT imaged performed with enteric and IV contrast demonstrates abnormal small bowel loops in the right lower quadrant (arrows). The bowel wall is thickened with submucosal edema and mucosal hyperenhancement compatible with enteritis.

antibiotic-associated diarrhea (125–127). Because of continued reports of vancomycin-resistant bacteria (129), the use of oral vancomycin is restricted in many hospitals. However, response to metronidazole has been compromised in part with the emergence and spread of hypervirulent North American Pulsed Field type 1 (NAP1) *C. difficile* strains in the United States and Europe (130). Most institutions are currently following IDSA guidelines for moderate and severe CDAD, oral vancomycin should be given to only patients with strong suspicion or proven CDAD and those who have not responded to metronidazole mild *C. difficile* associated illness. Some patients may require repeated or prolonged courses of metronidazole or oral vancomycin particularly if their clinical course necessitates continuation of the provocative agent (i.e., continued antibiotics or chemotherapy). Antidiarrheal compounds such as Lomotil® or Imodium® should not be

FIGURE 29.12. A 67-year-old woman with *Clostridium difficile* colitis. The patient had a history of recurrent ovarian cancer with associated sigmoid colon obstruction. She underwent sigmoid resection and diverting colostomy and a long course of antibiotics and developed abdominal pain, fever and diarrhea. Coronal CT performed with enteric and IV contrast demonstrates mural thickening of the colon with mucosal hyperenhancement, compatible with colitis. *C. difficile* titers were positive.

given routinely. If, however, diarrhea persists after appropriate tests and cultures, symptomatic therapy should be considered. Nitazoxanide is a nitrothiazolide and effectively treats intestinal infestation of *Cryptosporidium* and *Giardia* species; at low concentrations, nitazoxanide also inhibits *C. difficile*. A recent trial showed that nitazoxanide 500 mg twice daily was as effective in eradicating *C. difficile* as metronidazole given 250 mg 4 times daily (131). Nitazoxanide may be used for patients with metronidazole-refractory or recurrent *C. difficile* colitis although in our experience clinical efficacy of nitazoxanide in patient who had failed first-line anti CDI drugs remains less favorable. In a recent trial fidaxomicin (200 mg twice daily) or vancomycin (125 mg 4 times daily) orally for 10 days was assessed for clinical response and early relapses (132). The overall response was comparable for both treatment groups; patients treated with fidaxomicin had significantly lower rate of recurrence of *C. difficile* infection associated with non-NAP1 (nonvirulent) strains (132). Currently, this option is being used in patient with relapsed CDAD or those with high risk for relapsed infection.

Noninfectious Causes of Fever

Not all patients with gynecologic malignancy and fever have an infection. Pulmonary embolus, drug-related fever, and

tumor-related fever represent the main noninfectious sources of fever, but others, such as factitious fever and underlying collagen vascular disorder, autoimmune disorders and foreign-body type hypersensitivity reaction must also be considered. The use of biologic markers such as procalcitonin (PCT) and neopterin levels has been suggested to help distinguish between infectious versus noninfectious causes of fever, although further studies are needed to validate these tests prior to routine clinical use (133). Similarly, soluble triggering receptor expressed on myeloid cells-1 (sTREM-1) along with PCT have been suggested to improve recognition of patients with true infection and may facilitate decisions of whether or not to start empiric antimicrobial therapy (134). Unfortunately, neither PCT nor sTREM-1 by itself has shown consistent in differentiating infectious conditions versus tumor or treatment related febrile response. However, it is postulated that combination of systemic PCT and local and/or systemic sTREM-1 or CRP and/or neopterin may provide distinguishing patients with infection from those with noninfectious illness. Results from several randomized intervention studies on PCT-guided antimicrobial therapy in sepsis or pneumonia show PCT may aid in clinical decision making (134,135). At present, randomized trial to assess role of select biomarker panel including PCT, neopterin, and sTREM-1 are lacking.

Pulmonary embolus should be considered in a bed-bound or postoperative patient with any combination of fever, chest pain, dyspnea, or an abnormal chest radiograph. Patients with bulky pelvic tumors are also at risk. A high level of suspicion is important, and spiral intravenous contrast-enhanced chest CT scans or ventilation-perfusion scans may establish the diagnosis; in rare instances, a more definite pulmonary angiogram may be performed. Therapy remains anticoagulation with low-molecular-weight heparin. For patients who are unable to tolerate these drugs or who continue to have pulmonary emboli despite therapy, inferior vena caval filters are required.

Many drugs including antibiotics may cause fever (136). Patients typically develop fever and a diffuse maculopapular rash after several days of therapy. Eosinophilia, although a helpful sign, is usually lacking. Mild elevations in liver function tests may be present though nonspecific. Atypical presentations of drug fever, including patients without rash or those who develop fever weeks into therapy or after completion of therapy, can also occur. The diagnosis is usually made by discontinuing the antibiotic and observing the patient. It is important to remember that some drug fevers may take as long as a week to resolve. Supportive measures, such as antipyretics and antipruritics, may decrease symptoms.

The diagnosis of tumor fever can be made only after systematic exclusion of all other potential causes of fever. Most patients with tumor fever have metastatic disease involving the liver or lung. In these patients, the fever may be as high as 40°C, and chills may be absent; when not febrile, these patients often feel relatively well. In patients suspected of having tumor fever, a clinical trial of broad-spectrum antibiotics is given. If the fever does not abate and no other clear infection source is evident, the likelihood of tumor fever increases. Nonsteroidal anti-inflammatory agents such as naprosyn often produce an immediate and sustained response when administered to patients with tumor fever. This should only be done after infectious causes of fever have essentially been excluded, and a trial of broad spectrum antibiotic therapy has not resulted in defervescence.

Management of Acute and Chronic Complications of Gynecologic Cancer Treatment

ANDREAS OBERMAIR ■ OKECHUKWU A. IBEANU ■
DANIELLE D. JANDIAL ■ DEBORAH K. ARMSTRONG ■
ROBERT E. BRISTOW

GENERAL COMPLICATIONS OF GYNECOLOGIC CANCER SURGERY

Stroke

Stroke is estimated to occur following gynecologic oncology surgery in less than 1% of patients. Risk factors reflect those in the general population: history of previous stroke or transient ischemic attack (TIA), atherosclerosis, hypertension, diabetes, and advanced age (1). The etiology of stroke is attributed to hypoperfusion injury, hemorrhage, or embolism. In contrast to cardiac surgery, the majority of noncardiac stroke is due to cerebrovascular thrombosis, rather than embolic events (2). Hypotension (relative to the patient's baseline blood pressure) increases the risk of stroke in patients undergoing noncardiac, nonneurological surgery (3,4). Despite this, no evidence is available that intraoperative monitoring or regulation of blood pressure reduces the incidence of stroke. Avoidance of severe hyperglycemia and hypoglycemia is recommended, though there is a lack of consensus regarding glucose targets (2).

Cardiac events

Major noncardiac surgery is associated with major cardiac events (cardiac arrest, myocardial infarction, heart failure, arrhythmias) in 0.5% to 3.0% (3,5). Postoperative myocardial infarction is associated with 50% to 70% mortality rate and carries a high risk for future cardiac events. More than half of perioperative myocardial infarctions are unrecognized (asymptomatic non-ST elevation), and the incidence peaks during the first 24 hours postoperatively. Recent myocardial infarction, heart failure, ischemic heart disease, diabetes, renal insufficiency, cerebrovascular disease, obesity, sleep apnea, and poor functional status constitute high-risk factors.

Prevention of perioperative cardiac events should focus on evaluation of risk factors, risk stratification, and maximization of patient function. Good evidence supports the continuation of β -blockers and HMG-CoA reductase inhibitors ("statins") throughout the perioperative period for patients already treated with β -blockers. Perioperative measures should focus on maintenance of normothermia and postoperative monitoring of serum troponin levels.

Deep Vein Thrombosis and Pulmonary Embolism

Deep vein thrombosis (DVT) and/or pulmonary embolism (PE) comprise the spectrum of complications known as venous

thromboembolism (VTE). VTE following surgery is the most common cause of peri- and postoperative death (6). DVT affects 0.1% of patients each year, but the incidence is significantly higher among patients undergoing surgical treatment for gynecological cancer, occurring in up to 20% of cases (7).

Patients with gynecologic cancer are at high risk for VTE because of their underlying malignancy, increased age, and extensive nature of treatment. The underlying mechanism of disease includes increased release of procoagulant factors, cytokine imbalance, and activation of the antifibrinolytic pathways. Clinical risk factors include a history of VTE, obesity, immobility, trauma, prolonged surgical time, radiation therapy, and increasing complexity of surgery. Patients with the highest risk for developing postoperative VTE have 2 or more of the following: age greater than 60 years, malignancy, and history of VTE (8). Early ambulation, heparin, low-molecular-weight heparin, and sequential compression devices (graduated compression stockings or intermittent pneumatic compression) are effective in reducing the incidence of VTE (9). The incidence of VTE in patients undergoing major gynecologic cancer surgery is decreased with dual, prolonged (4-week) prophylaxis without increasing bleeding complications (10). Current guidelines recommend VTE prophylaxis for at least 4 weeks following surgery in the absence of bleeding or other contraindications.

Bladder and Ureteral Injury

Injuries to the lower urinary tract (laceration, transection, crush injury, ligation, thermal injury, injury through devascularization) are uncommonly diagnosed intraoperatively; the outcomes of patients who are diagnosed late (urinomas, peritonitis, sepsis, fistula) are worse (11). The risk of bladder/ureter injury ranges between 1.1% and 5.3% in patients requiring a radical hysterectomy and is approximately 1% for standard hysterectomy for uterine cancer (11–14). Bladder injuries recognized at the time of the initial surgical procedure should be repaired immediately using a standard 2-layered closure of delayed absorbable suture. Bladder injuries diagnosed postoperatively (e.g., fistula) may be treated with an indwelling catheter for a period of several weeks. If spontaneous closure does not occur with prolonged drainage, surgical repair is indicated. Ureteral injuries recognized intraoperatively should be repaired by excising the injured segment of ureter, placement of a ureteral stent, and reapproximating the distal urinary tract (ureteroureterostomy, ureteroneocystostomy with psoas hitch, and possibly a Boari flap). Ureteral injuries detected remote from the incident surgical procedure can be managed by attempted placement of a ureteral stent, which can be accomplished either retrograde via cystoscopy or antegrade via a percutaneous nephrostomy tube.

If spontaneous closure does not occur after an observation period of 4 to 6 weeks, or if stent placement is not feasible, surgical repair is indicated. Long-term outcomes are generally excellent.

Injury to Small and Large Bowel

Bowel injuries occur in approximately 1% of patients undergoing surgery for gynecologic cancer. Risk factors include previous surgery, adhesions, and previous radiotherapy. Most bowel injuries are recognized at the time of surgery. The general principles of management include that any bowel anastomosis (hand-sewn or stapled) needs to be patent, tension-free, and well-vascularized. If any of these 3 conditions is unmet, the risk of leakage is very high. Small or large bowel injuries require primary bowel resection if the blood supply to the bowel is compromised or if injuries occurred at multiple levels.

Nerve Injury

Poor patient position, improper placement of retractor blades, and radical surgical dissection increase the risk of nerve injury (11). *Neurapraxia* is caused by compression leading to changes in intraneural microcirculation and is fully reversible. *Axonotmesis* (crush injury) will sever axons and function will resolve with gradual regeneration of nerve fibers. Transection of nerve fibers causes aberrant regeneration of the axons (misalignment), resulting in permanent functional losses.

The lumbosacral plexus is at risk for injury during gynecologic surgery. The use of short retractor blades or flexible blades with packs placed under the blades instead of self-retainers may reduce the risk of nerve injury intraoperatively (11). Additionally, avoidance of long-term hip extension (femoral nerve) or if flexion (sciatic nerve) in lithotomy position will decrease the risk of nerve injuries.

Hemorrhage

Intraoperative hemorrhage is defined as blood loss greater than 1,000 mL or if there is a requirement for intraoperative blood transfusion. Significant hemorrhage can be expected in 4% to 7.5% of patients undergoing surgery for advanced ovarian cancer (15). Risk factors include anemia prior to surgery, history of prolonged bleeding, blood-thinning medication and herbs/supplements, and intraoperative hypothermia. The principles of management of intraoperative hemorrhage include tamponade (packs) or atraumatic grasping and control of all feeding vessels; identification of sensitive structures (ureters, nerves); dissection of bleeding sources; correction of coagulopathy; the selective use of sutures, clips, diathermy, patches; and the use of topical hemostatic agents. Internal iliac artery ligation and hysterectomy should be considered if other measures fail. Finally, “damage-control” surgery, with placement of pelvic packing, transfer to the intensive care unit for stabilization, and return to the operating room for pack removal after 24 to 48 hours, may be a last resort.

Postoperative Ileus

Postoperative adynamic ileus is delayed gastrointestinal tract recovery; it may impair wound healing and lower the threshold for infections. Gastrointestinal motility is controlled by the enteric autonomous nervous system and influenced by neural reflexes (interfered by regional anesthesia), inflammation/trauma (tissue handling) and neuro-humoral substances (systemic analgesia). Medical illnesses (e.g., diabetes mellitus) or medications may increase the risk of ileus.

Differentiating postoperative ileus from a mechanical small bowel obstruction (SBO) is critical. Rapidly progressive systemic (septicemia) and abdominal symptoms (peritonitis, feculent vomiting) point to the likelihood of SBO. Bowel sounds are an unreliable indicator and are usually quiet or absent with ileus, but may be high-pitched or absent with SBO. Computed tomography (with oral gastrografin) is recommended to help differentiate ileus from SBO. The treatment of ileus is conservative and nonsurgical, and includes restriction of oral intake, nasogastric tube suction, intravenous fluid and electrolyte replacement, and discontinuing systemic opioids if possible. Total parenteral nutrition (TPN) should be considered after 7 to 10 days without satisfactory oral nutrient intake.

Postoperative Small Bowel Obstruction

Postoperative SBO results from a mechanical blockage of intestinal motility. Possible causes include herniation of bowel (port sites, internal herniation), early adhesions, intussusceptions, and small bowel tumors. The characteristic presentation of SBO is that patients initially recover well (pass flatus, tolerate oral intake), but then develop nausea, vomiting, abdominal discomfort, and pain. Computed tomography will show a site of bowel obstruction (transition point), gaseous distension of small bowel, and paucity of air in the rectum. Effective management requires an expedited diagnosis followed by a short (72 to 96 hours) conservative trial of nasogastric suction and fluid resuscitation. If there is no improvement after this period, surgical intervention is warranted. Protracted delays may cause secondary problems, such as bowel ischemia and necrosis.

Surgical Site Infection

Surgical site infections (SSI) lead to delayed wound healing, revision surgery, increased use of antibiotics, and increased length of hospital stay (16). On average, a patient with SSI spends 7 days longer in the hospital, is 60% more likely to spend time in the ICU, is 5 times more likely to be readmitted within 30 days of discharge, and is twice as likely to die (17). The incidence rates vary depending on patient factors and type of surgery, and range from 2% to 10% after laparotomy, while the rate is lower with minimally invasive surgery. Risk factors for SSI include concomitant systemic disease (diabetes, anemia, immunosuppression, immunosuppressive therapy with radiotherapy, chemotherapy, or steroids), obesity, advanced age, preexisting infection, hematoma, damaged tissue, extensive surgery, hypothermia, hemorrhage, and use of drains or catheters (18). Infection control programs reduce the rates of SSI by 35% to 41%, to 35% (19). Prophylactic antibiotics are most effective when administered 30 to 60 minutes preoperatively. A preoperative Chlorhexidine shower is as effective as bar soap or detergents. Trials on antibacterial sutures are ongoing.

DISEASE SITE-SPECIFIC SURGICAL COMPLICATIONS

Surgery for Ovarian Cancer—Cytoreductive Surgery

Acute Complications

Ovarian cancer cytoreductive surgery has evolved to a contemporary approach designed to achieve complete cytoreduction, with an accepted increase in morbidity balanced against the maximal benefit on long-term survival. A comprehensive approach

to advanced-stage ovarian cancer must address disease not only in the pelvis, but also frequently involves surgery on the large and small bowel, diaphragm, liver, spleen, and distal pancreas. Recognition and management of associated perioperative complications is critical. The morbidity of extensive surgical debulking is increased with age, poor nutritional status, and poor functional status (20–24).

The *en bloc* resection of locally advanced ovarian cancer (radical oophorectomy or modified posterior exenteration) carries an operative mortality of 0% to 8%, with more contemporary series reporting rates of 4% or lower (25–27). Wound complications are seen in 6% to 34% of patients, particularly with severe hypoalbuminemia (<3.0 ng/dL) and large-volume ascites (28). The estimated blood loss with radical oophorectomy ranges from 800 to 2900 mL, with as many as 87% of patients receiving blood product transfusion.

Intestinal complications with radical debulking are among the most commonly encountered, with prolonged ileus reported in up to 40% of patients. A large series of 587 patients recently reported an average incidence of postoperative ileus of 30.3% (25.9% without bowel resection, 38.5% with bowel resection) (29). The pattern of spread of ovarian cancer results in the need for bowel resection in 19% to 54% of cases (30,31). Colorectal anastomotic leak occurs in fewer than 4% of cases and can lead to abscess, fistula formation, sepsis, and reoperation; the mean time to diagnosis is 19 days (range, 4 to 32 days) (25,26,31,32–34). Anastomoses below the peritoneal reflection and less than 7 cm from the anal verge are at the highest risk for failure (35). While there are limited data in gynecologic oncology patient populations, randomized studies on the management of colorectal disorders suggest that mechanical bowel preparation does not lower the risk of anastomotic leak. A recent meta-analysis of 18 randomized controlled trials with over 5,800 patients confirmed that administration of mechanical bowel preparation yielded no difference in anastomotic leak rates (4.4% vs. 4.5%; odds ratio [OR], 0.99 [0.74, 1.13]) or wound complications (9.6% vs. 8.5%; OR, 1.16 [0.95, 1.42]) (36). Studies of intraperitoneal pelvic drain placement in the setting of a rectal anastomosis similarly suggest no benefit to lowering the risk of anastomotic leak (37). While the value of pelvic drainage in reducing anastomotic leak has not been demonstrated, drainage may still be useful in the prevention of pelvic fluid collections, abdominal compartment syndrome from re-accumulation of large-volume ascites, infected hematomas, and urinomas following urinary tract resection. Finally, intestinal diversion has historically been utilized for protection of a rectal anastomosis during primary cytoreductive surgery. Older data suggest that up to 59% of patients requiring rectal anastomosis also underwent protective intestinal diversion with colostomy or ileostomy. Based on more contemporary data, intestinal diversion to “protect” a colorectal anastomosis is not routinely required but may be advisable in patients with very low anastomoses, technically suboptimal anastomoses, or severe hypoalbuminemia (21% leak rate with albumin <3.0 g/dL vs. 3.4% leak rate with albumin >3.0 g/dL) (26,33). Initial management of anastomotic leak includes antibiotic therapy and percutaneous drainage under image guidance. If conservative management is unsuccessful, surgical exploration and diversion are required.

Upper abdominal procedures including splenectomy, distal pancreatectomy, partial hepatectomy, and diaphragmatic peritonectomy or full-thickness resection may be required to render a patient completely free of visible disease. Development of pleural effusions following diaphragmatic peritonectomy or resection occurs in 9% to 64% of patients, although these can be managed with thoracentesis alone in the majority of symptomatic patients. When full-thickness resections are required, perioperative morbidity has been reported in as many as 20% of patients (38,39). A small postoperative pneumothorax will frequently resolve spontaneously and can be monitored with daily chest radiographs.

Chest tube placement is occasionally required for major resections of the right hemidiaphragm, large pleural effusions, or worsening pneumothorax.

Acute complications associated with splenectomy include hemorrhage, left lower lobe atelectasis, splenic vein thrombosis, arteriovenous fistula between the splenic artery and vein, and infectious morbidity (40,41). Overwhelming postsplenectomy infection, most commonly due to *Streptococcus pneumoniae*, is a serious complication with a prevalence of 3.2% and a mortality rate as high as 70% (42). Vaccinations for pneumococcus, meningococcus, and *Haemophilus influenza* type B are the cornerstones of prevention.

Distal pancreatectomy is occasionally indicated to achieve complete disease resection and can result in pancreatic fistula (leak) and pancreatic pseudocyst formation (30,43). Intraoperative placement of a closed suction drain in the left upper quadrant can be useful to monitor for signs of early fistula formation as well as prevent pseudocyst formation. Mild enzyme leakage has little clinical impact and can be managed with prolonged drainage and standard oral feeding. Enzyme leakage greater than 3-fold the upper limit of normal or the presence of pain, fever, or leukocytosis requires delay of oral nutrition, administration of antibiotics, somatostatin analogues, and parenteral nutrition.

Chronic Complications

Ovarian cancer patients may experience long-term sequelae related to prior cytoreductive surgery, often exacerbated by the presence of disease recurrence or carcinomatosis. More commonly encountered complications requiring operative intervention are mechanical bowel obstruction or anastomotic stricture. SBO in ovarian cancer patients is best approached with an extended trial of bowel rest and decompression with nutritional supplementation unless bowel dilation is greater than 5 cm, at which point the risk of perforation increases. Carcinomatous ileus can be confused with mechanical bowel obstruction; however, this condition is unlikely to be surgically correctable. If mechanical SBO is refractory to conservative measures, surgical options include resection with reanastomosis, diverting ileostomy, enterocolonic bypass, or palliative percutaneous gastrostomy. Associated complications may include anastomotic failure, blind loop syndrome, or short gut syndrome. Finally, late complications may follow extensive resection of the ileum or a right hemicolectomy; these late complications include chronic diarrhea from impaired absorption of water, fat, and bile salts, and problems related to poor absorption of nutrients, including the fat-soluble vitamins and vitamin B₁₂.

Surgery for Uterine Cancer

Acute Complications

Until recently, total abdominal hysterectomy (TAH) was considered the standard surgical approach to hysterectomy for uterine cancer. However, minimally invasive surgical techniques have become increasingly popular due to their favorable outcomes in treatment. To date, three prospective randomized controlled clinical trials are available to compare outcomes from open and laparoscopic surgery for uterine cancer (12–14). The Gynecologic Oncology Group (GOG) LAP2 Trial (GOG 222) recruited a total of 2,616 women (12). Patients were eligible if they had clinical stage I to IIA uterine cancer; all histological cell types were allowed and all patients had to have pelvic and aortic lymph node dissection. The Australian LACE Trial enrolled 760 patients. Patients were eligible if they had endometrioid cell type, clinical stage I disease. Patients were not eligible if they had a uterine size larger than 10 weeks gestation, had evidence of extrauterine spread (ovarian masses, enlarged lymph nodes), or were unfit for surgery

due to medical comorbidities (14). The Dutch TLH Trial aimed to compare outcomes in early-stage endometrial cancer treated by laparoscopy or laparotomy. Patients with early-stage endometrial cancer (endometrioid cell type, FIGO grade 1 or 2, clinically stage I disease, negative endocervical curettage) or complex endometrial hyperplasia with atypia were eligible (13). Intraoperative surgical complications were comparable in all 3 trials.

In the LAP2 trial, postoperative surgical complications were significantly more common in patients who had a laparotomy than in patients who had a laparoscopic procedure (21% vs. 14%). Postoperative ileus (8% vs. 4%) and cardiac arrhythmia (2% vs. 1%) were significantly more common in patients in the open/laparotomy group. In the LACE trial, the open/laparotomy group had a 44% higher incidence of postoperative complications (18.6% in open, 12.9% in laparoscopic) compared to patients in the laparoscopy arm. The incidence of serious adverse events was 74% higher in the open group compared to the laparoscopy group (14.3% for open, 8.2% for laparoscopy). Wound infections or dehiscence were the main contributors to the difference in postoperative complications between laparoscopic (2.0%) and open (8.9%) groups. An open surgical approach (laparotomy), higher Charlson's medical comorbidities score, moderately or poorly differentiated tumors on curetting, lower performance status prior to surgery, obesity, and anemia were independently associated with an increased risk for surgical adverse events (44). Patient's age at surgery was not a risk factor for surgical complications. The Dutch TLH trial recorded comparable postoperative surgical complications in the open and the laparoscopic group (10.6% open/laparotomy; 11.9% laparoscopy). Interestingly, the incidence of postoperative complications was similar among all 3 trials for patients randomized to the laparoscopic arm (ranging from 11.9% to 14%). In contrast, the incidence of postoperative complications in the open/laparotomy arm was significantly lower in the Dutch TLH trial (10.6%) compared to LACE (18.6%) or LAP2 (21%). In the Dutch TLH trial, no patient required a retroperitoneal node dissection, whereas in the U.S. LAP2 trial, all patients had to have a pelvic and aortic lymph node dissection. In the Australian LACE trial, approximately half of patients had a retroperitoneal node dissection; however, no differences in the incidence of acute surgical complications were observed between the treatment arms when stratified by nodal dissection status.

Chronic Complications

Lymphedema and lymphocele are the main chronic complications following surgery for uterine cancer, and the incidence varies depending on the type of surgery and extent of lymph node removal. Overall, lymphedema occurs in 20% of patients following hysterectomy with lymphadenectomy (45). Obesity, number of lymph nodes removed, extent of surgery, postoperative infection, radiation therapy, and postoperative DVT increase the risk of developing lymphedema. Lymphoceles are an accumulation of lymphatic fluid in dead space due to postoperative leakage of lymphatic fluid coupled with incomplete lymphatic reabsorption. Most lymphoceles are asymptomatic and found incidentally. Its true incidence is therefore unknown (range, 0% to 58.5%) (46–48).

Surgery for Cervical Cancer:Radical Hysterectomy and Pelvic Exenteration

Acute Complications

Radical hysterectomy for early-stage cervical cancer is associated with a major complication rate (excessive blood loss, urinary/gastrointestinal tract injury, nerve injury) of 5% to 10%. Ureterovaginal fistula occurs in 2% to 3% of cases and typically presents within 14 days of surgery with watery leakage

per vagina commonly associated with pain or fever (49). A computed tomography urogram is usually diagnostic. Instillation of methylene blue dye intravenously or via retrograde instillation into the bladder can also help to distinguish a vesicovaginal from ureterovaginal fistula by observing for extravasated dye onto a vaginal tampon. Ureterovaginal fistulas can be managed in most cases with ureteral stenting or percutaneous nephrostomy. Vesicovaginal fistulas occur in 1% to 3% of cases, and can often be managed with prolonged catheterization and continuous decompression of the bladder for 4 to 6 weeks. For nonhealing fistulas, larger fistulas (>1 cm), or complex fistulas involving both ureter and bladder, surgical management with closure is indicated. This can be approached vaginally with a Latzko partial colpocleisis if the defect is small, apical, and not in proximity to the ureter. Bulbocavernosus or Martius fat pad grafts can also be used (50). Trigone involvement or larger complex fistulas are best approached abdominally with a layered closure and an omental flap. Urinary retention due to sensory loss and voiding dysfunction are well-recognized complications of radical hysterectomy and result from the denervation of the bladder during the parametrial dissection. Most patients are managed with prolonged bladder decompression for 3 to 7 days with a transurethral or suprapubic catheter. A retrograde voiding trial is recommended to assess for bladder function prior to removal of the catheter, and postvoid residual values of 40 to 50 mL are generally acceptable. Minimally invasive approaches to radical hysterectomy, including both traditional laparoscopic and robotically-assisted techniques, may offer several health-related benefits including less pain, shorter hospital stay, and more rapid return to full activity than the abdominal approach. However, the incidence of vaginal cuff complications/dehiscence (1.6% to 4.1%) may be higher than that observed with laparotomy (<0.5%) (56–60); there is also a potential higher risk for nerve injuries (51,52).

Total pelvic exenteration (TPE) is primarily indicated as salvage therapy for cervical cancer patients who have failed radiation therapy or require combined treatment of recurrence in the central pelvis. Acute perioperative morbidity related to TPE is high, with up to 75% of patients experiencing a major complication; mortality rates of 1% to 5% are typical. Furthermore, reoperation rates to address major complications are high, with rates of 16% to 25.6% reported in the literature (53,54). Morbidity of TPE is attributable to long operative times, compromised healing of the irradiated field, and the complexity of the surgical reconstruction. Significant blood loss, infectious morbidity primarily involving the urinary tract, sepsis, wound complications, fistulas, ileus, and anastomotic leaks of the intestinal or urinary anastomosis are some of the more commonly reported complications. Sepsis, adult respiratory distress syndrome, heart failure, pulmonary embolus, and multiorgan system failure are typical terminal events. The acute complication rate for both urinary continent and incontinent and urinary diversion ranges from 17% to 20%; these complications include urinary leak, fistula, or anastomotic failure (55). Such problems can be managed conservatively in many cases with prolonged conduit drainage and diversion with percutaneous nephrostomy. Refractory leaks may require surgical revision of the reservoir. Despite the high risk of complications, 5-year survival is in the range of 50% (54,56,57).

Chronic Complications

Urinary retention following radical hysterectomy is usually self-limited; however, long-standing bladder dysfunction may require patient intermittent self-catheterization. Long-term rectal dysfunction is similarly encountered and manifests as constipation or urgency. Nerve-sparing radical hysterectomy, which preserves autonomic and splanchnic innervation to the bladder and rectum, has been reported to decrease bladder and rectal morbidity (49,58). Ureteral strictures are encountered in 1% to 3% of patients and may present with fever and pain, but may be

asymptomatic and can lead to loss of renal function. Management is with ureteral stent placement, if possible, or percutaneous nephrostomy placement. Occasionally reoperation with ureteral reimplantation can be required. Colonic stomas may be prone to prolapse, hernia, or stricture. However, the most commonly reported intestinal complication is bowel obstruction. Unlike early postoperative bowel obstruction, late obstructions are more likely due to adhesive disease or disease recurrence. Sexual dysfunction is an underreported long-term side effect following radical hysterectomy (59).

Patients undergoing pelvic exenteration are at risk for a number of long-term complications. Urinary diversions are prone to stomal stricture, chronic urinary tract infection, renal dysfunction, nephrolithiasis, metabolic alterations, and difficulty with accessing the reservoir (56,57). Reestablishing intestinal continuity after exenteration has been advocated to minimize the long-term psychosocial and quality-of-life issues surrounding 2 permanent abdominal stomas but has been associated with a higher risk of reoperation (50% to 60%) and disease recurrence (57). Sexual dysfunction and distorted body image are common problems associated with pelvic exenteration.

Surgery for Vulvar Cancer

Acute Complications

Surgical innovation in vulva cancer evolved as a response to minimize the risk of surgical complications associated with the *en bloc* radical vulvectomy and bilateral inguinal lymphadenectomy popularized by Stanley Way in the 1950s, rather than from a concern about poor survival outcomes. Vulvar or groin wound breakdown occurs in as many as 50% of patients following radical vulvectomy (60–62). Development of a wound infection is predictive of future wound breakdown and lymphedema (61). Risk factors include increased patient's age, obesity, diabetes mellitus, smoking, and prior radiation to the groin. The use of myocutaneous flaps can reduce tension on suture lines, prevent wound breakdown, infection, and improve cosmetic and functional outcome. A nonrandomized, prospective study showed a reduction in wound breakdown for patients undergoing radical vulvectomy with lymph node dissection and hyperbaric oxygen therapy (63).

Contemporary management of vulvar cancer is tailored to the size and location of the primary tumor and generally consists of radical partial vulvectomy or wide radical excision combined with ipsilateral or bilateral inguinal lymphadenectomy through separate groin incisions (64). The incidence rates of wound infection, cellulitis, and wound breakdown are 21% to 39%, 21% to 57%, and 17% to 39%, respectively. Optimizing glucose control in patients with diabetes mellitus, using appropriate antibiotic prophylaxis, and sparing the saphenous vein are important prevention strategies (65). Sentinel lymph node biopsy (SLNB) is an emerging technique that has been associated with a reduction in groin wound breakdown (11.7% vs. 34%) and cellulitis (4.5% vs. 21.3%) compared to systematic groin node dissection (66).

Chronic Complications

Chronic complications from vulvar cancer surgery are often a result of groin node dissection. As many as 50% of patients requiring a groin dissection will experience a long-term complication related to the procedure. Lymphedema occurs in 14% to 48% of patients and presents as leg swelling or heaviness of the lower limbs (67). It results in an inability to perform daily activities, impacts on psychological and social well-being, and represents a significant financial burden associated with the treatment (68). Obesity, the number of lymph nodes removed, extent of surgery, postoperative infection, radiation therapy to the groins, and postoperative DVT increase the risk of developing

lymphedema after groin dissection (69). SLNB has been associated with a 1.9% incidence rate of lymphedema, compared with 25.2% in patients undergoing systematic groin dissection (66). Lymphocele formation develops in 7% to 19% of patients after inguinal-femoral lymphadenectomy (60).

Over half of women who undergo vulvectomy report sexual dysfunction and psychological issues resulting in dyspareunia, problems with micturition, negative feelings about body image, decreased desire, and inability to orgasm (68). Providing information before and after surgery that details how the treatment may affect sexuality and change anatomy, as well as the provision of methods for how to cope with feelings regarding the illness; may decrease anxiety. The FACT-V questionnaire is a valid and reliable tool that can measure the impact of treatment on QOL and improve standardization or quality of life research efforts.

Surgery in the Irradiated Field

Radiation induces a complex series of tissue changes including vascular sclerosis and tissue ischemia, the end result of which is fibrosis. Tissue planes are obliterated and healing is compromised. It is estimated that approximately 5% to 7% of patients who undergo radiation therapy for cervical cancer will experience major treatment complications that require surgery (70). The most common sites of intestinal injury in patients who undergo pelvic irradiation are areas that typically lie in the pelvic field. The ileum is the most frequent site of injury, because of the greater radiosensitivity of the small intestine compared with the colon. The most common indications for reoperative surgery in patients irradiated for cervical or endometrial cancer are intestinal obstruction (44%) and intestinal fistula or perforation (32%). Radiation damage frequently leads to matted loops of distal ileum densely fixed in the pelvis associated with obstruction or fistula. In the setting of intestinal necrosis, perforation, or abscess formation, resection should be attempted if it can be done without undue risk of damage to adjacent structures. Alternative more conservative approaches such as intestinal bypass procedures are less morbid but may lead to the development of blind-loop syndrome or result in subsequent spontaneous perforation or fistula formation. In a series of 77 patients who underwent surgery for radiation injury to the small intestine, no difference in short-term complications was noted whether patients underwent resection or bypass (71).

Urinary tract complications that may lead to surgery in a previously radiated patient include radiation-induced nonhealing or complex ureterovaginal or vesicovaginal fistulas and ureteral strictures, which compromise renal function. Asymptomatic stricture is likely more common and underreported in the literature and may lead to a silent loss of renal function. Many cases of radiation injury to the lower urinary tract can be managed conservatively with ureteral stent placement, percutaneous nephrostomy, or attempts at endoureteral dilation. Recurrent cancer must always be considered and the appropriate diagnostic biopsies and imaging obtained prior to consideration for surgical correction or urinary diversion (72).

ACUTE AND CHRONIC COMPLICATIONS OF RADIATION THERAPY FOR GYNECOLOGIC CANCERS

Radiation therapy plays a major role as a primary, adjuvant, and palliative treatment of cancers of the cervix, vulva, vagina, and endometrium. Notable progress has been made in the treatment of locally advanced cervical cancers, with the addition of radio-sensitizing chemotherapy based on

demonstrated improved patient outcomes in multiple studies (73–75). Vaginal brachytherapy is also increasingly being delivered using high-dose-rate (HDR) application. Unfortunately, external beam pelvic radiation therapy and brachytherapy are associated with effects on normal tissues, with subsequent acute and chronic manifestations that may adversely affect patients' quality of life, and pose limitations to treatment.

Acute effects usually develop beyond a radiation dose of 2000 Gy, and symptoms present within 4 weeks of starting treatment, while chronic effects are usually diagnosed after 1 month of completion of therapy. Normal tissue tolerance, volume of tissue irradiated, total dose received, dose fractions, as well as the arrangement of radiation treatment fields; are treatment-related factors that determine the severity of radiation effects in normal tissues. In addition, age, tobacco use, and chronic diseases such as diabetes, hypertension, peripheral vascular disease, and prior inflammation can influence the onset and severity of postradiation symptoms. The most common acute and chronic complications of radiation therapy in gynecologic cancers occur in the gastrointestinal tract, lower urinary tract, and reproductive tract (76). The GOG and Radiation Therapy Oncology Group (RTOG) use the National Cancer Institute Common Terminology Criteria for Adverse Events and the Common Toxicity Criteria for reporting the tissue effects and complications of radiation therapy. Table 30.1 shows the RTOG Morbidity Grading System. Normal tissue tolerance to therapeutic radiation varies by organ site (Table 30.2).

GASTROINTESTINAL TRACT AND URINARY BLADDER

Gastrointestinal symptoms and side effects are among the most common complications of radiation therapy. Intestinal cells have a fast doubling time of approximately 12 to 15 hours. Radiation induces acute gastrointestinal injury by causing acute mucosal inflammation and death of superficial intestinal cells with accompanying cytokine activation and release in the intestinal submucosa. These changes manifest as deepithelialization and ulceration, edema, erythema, and mucosal hemorrhage. Subsequently, there is mucosal ischemia with fibrosis and tissue hypoxia. In the chronic state, the intestinal mucosa appears pale and flat with multiple telangiectasias, and the bowel demonstrates decreased compliance and luminal capacity (77).

Table 30.1 Radiation Therapy Oncology Group Morbidity Grading System

Grade	Morbidity
1	Minor symptoms requiring no treatment
2	Symptoms responding to simple outpatient management; lifestyle (performance status) not affected
3	Distressing symptoms altering patient's lifestyle (performance status); hospitalization for diagnosis or minor surgical intervention (e.g., urethral dilatation) may be required
4	Major surgical intervention (e.g., laparotomy, colostomy, cystectomy) or prolonged hospitalization is required
5	Fatal complications

Small Bowel

Acute Complications

The normal tissue tolerance of the small bowel is 45 Gy. Acute symptoms begin above 20 Gy depending on the volume of bowel segment involved (78). Due to its mobility, the small bowel is typically spared during external beam pelvic radiation. In patients with relatively fixed bowel segments due to prior adhesions from surgery, the potential for small bowel injury is increased. Acute and subacute symptoms of radiation-induced small bowel injury usually manifest within 1 month of commencement of therapy. Common presentations include abdominal cramps and diarrhea, which may be bloody. Nausea and vomiting, anorexia, and abdominal cramps may dominate the clinical picture in patients with acute SBO. Disruption of the mucosal integrity and immunity can lead to bacterial overgrowth, malabsorption, and enteritis. Diarrhea can usually be managed successfully with antimotility agents such as loperamide, diphenoxylate, and kaopectate (77). Patients with serious electrolyte derangements and dehydration require more aggressive resuscitation. It is important to exclude *Clostridium difficile* colitis as a cause of symptoms prior to initiating antimotility therapy. Dietary adjustments in the form of a low-residue diet and low-fat diet can help in patients with malabsorption. Acute obstruction should be managed initially with bowel rest, nasogastric suction, hydration, electrolyte repletion, and nutritional support. Radiologic studies may identify areas of stricture or narrowing. Surgery is indicated in patients who do not respond to medical management, and those who develop peritonitis.

Chronic Complications

Chronic small bowel injury results in diarrhea, bleeding, malabsorption with nutritional deficiencies, pain, fistula formation, and radiation-induced SBO (Figure 30.1). Symptoms can appear years after therapy (78). Severe bleeding may require invasive therapy for control, in the form of endoscopic coagulation or segmental resection. Long-term nutritional adjustments may be necessary in order to combat vitamin deficiencies, bile acid malabsorption, dumping syndrome, and chronic caloric deficiency. In patients with satisfactory performance status and reasonable life expectancy, surgery may be undertaken to address chronic small bowel strictures. Enteric fistulas present a challenge to the patient and physician, and require a multidisciplinary management approach with nutritional and surgical teams experienced in the care of this complication. Radiation-induced fistulas are less likely to heal, and may require bowel diversion for symptom control.

Large Bowel

Acute Complications

The tissue tolerance of the rectum is 70 to 75 Gy. The relatively fixed position of the rectum and close relationship to the vaginal tube are major factors in rectal injury during pelvic radiation therapy, specifically vaginal brachytherapy. Radiation-induced proctitis occurs in 2% to 20% of patients following pelvic radiation (79,80). Similar to the small bowel, acute effects are caused by intestinal epithelial inflammation and cell loss, with mucosal edema, ulceration, and bleeding. Acute symptoms of diarrhea with mucus, bleeding, tenesmus, cramping, fecal urgency, and incontinence may be severe enough to interrupt treatment. Acute symptoms are usually self-limiting, but may require the use of antimotility agents, dietary adjustment (fiber), and hygiene measures for control. Typically, these symptoms subside significantly or stop within 3 months of onset.

Table 30.2 Normal Tissue Tolerance to Therapeutic Irradiation

Organ	TD 5/5 Volume			TD 5/50 Volume			Selected Endpoints

Chronic Complications

Chronic large bowel changes are due to obliterative endarteritis, mucosal ischemia, and fibrosis; with pale mucosa, telangiectasias, and ulcerations. Stricture and fistula formation are also potential sequelae. Rectal bleeding is a common presentation of chronic radiation proctitis, and can be severe in up to 6% of patients. Chronic proctitis may not be preceded by a history of acute proctitis, and is generally diagnosed in patients who develop symptoms at least 3 months after completion of radiation therapy. The anterior rectal mucosa is the usual site of bleeding from telangiectasias. Unlike in acute proctitis, lower gastrointestinal endoscopy (flexible sigmoidoscopy) is indicated in the evaluation of chronic proctitis. The most effective medical treatments for chronic radiation proctitis are sucralfate enema, metronidazole enema, and hyperbaric oxygen (77,81). Invasive

treatments for chronic proctitis involve the endoscopically assisted use of topical and ablative therapies. Surgery for radiation-induced proctitis carries high morbidity rates, and should be approached by surgeons experienced in performing technically complex bowel surgery in previously irradiated fields.

Fecal incontinence after radiation injury is a psychologically debilitating symptom that is underreported and also underassessed by treating physicians. A large population study from Sweden reported a 12% rate among patients treated with pelvic radiation and brachytherapy for gynecologic cancers (82). Self-reported rates of fecal incontinence and fecal urgency among patients treated with pelvic radiation and brachytherapy for gynecologic cancers are as high as 34% and 58%, respectively (83). Increasing dietary fiber can alter stool consistency and increase stool bulk. Patients can also use hygiene pads or diapers, and undergo pelvic floor therapy and toilet training. Rectal mucus discharge or seepage can similarly be addressed with toilet training and hygiene.

**FIGURE 30.1.** Radiation-induced small bowel obstruction.

Urinary Bladder

Acute Complications

Tissue effects in the urinary bladder are commonly observed following pelvic radiation. Due to difficulties associated with changes in volume and shape during treatment, calculations of dose tolerance have been imprecise; however, the quoted tolerance of the urinary bladder is between 65 to 80 Gy. Patients with acute radiation cystitis have irritative lower urinary tract symptoms, and bleeding. Mucosal inflammation is the hallmark feature (84). Before instituting a treatment regimen for presumed acute radiation cystitis, it is a good practice to exclude a lower urinary tract infection.

Chronic Complications

Radiation-induced ischemia and fibrosis can lead to chronic cystitis, with hematuria, decreased bladder capacity, urinary

urgency, frequency, and incontinence. Chronic severe urinary complications are relatively uncommon (1% at 5 years and 2% at 20 years) but can adversely impact patients' quality of life. Cystoscopic evaluation is appropriate prior to treatment; however, biopsies are not necessary unless atypical or unexpected findings are encountered (85,86). Medical management should suffice for most patients. Generally, antispasmodics like pyridium, as well as anticholinergics, and muscarinic receptor inhibitors can be used for irritative bladder symptoms. Patients with severely diminished bladder capacity can be managed with long-term indwelling catheters, or considered for urinary diversion if they are fit for surgery and have reasonable life expectancy. Formalin instillations into the bladder, cystoscopic fulguration, and hyperbaric oxygen therapy have been described for problematic bleeding and chronic cystitis respectively (87). Less commonly, urinary tract fistulas can occur between the bladder and colon, rectum, or vagina. Conservative management is usually not successful in the management of radiation fistulas, and urinary diversion may offer the only reasonable chance of symptom control. Prior surgery, inflammatory bowel disease, and smoking can adversely impact on treatment outcomes following surgical treatment.

REPRODUCTIVE TRACT

Vagina and Sexual Side Effects

Acute Complications

The vagina is a relatively radio-resistant structure, with a tolerance of up to 140 Gy. Radiation effects on the vaginal mucosa have traditionally been assessed in the proximal vagina, which has a lower dose limit of 120 Gy following external beam and brachytherapy (88). Acute manifestations of radiation injury include epithelial desquamation, redness, and dryness. The incidence of grade 1 and 2 vaginal toxicity is 10% among patients receiving external beam pelvic irradiation and vaginal brachytherapy for gynecologic cancers, while grade 4 toxicity occurs in 3.6% of patients (89).

Chronic Complications

Late radiation effects on the vagina lead to mucosal pallor, telangiectasias, loss of elasticity, and diminished lubrication. Agglutination of the vaginal apex can lead to vaginal narrowing and shortening. Problems with vaginal lubrication, decreased capacity, and mucosal thinning impact on sexual functioning; they account for a significant amount of morbidity and loss of quality of life in patients with cervical and vaginal cancers who are irradiated. Sexual intercourse should be encouraged in patients who are able to resume intercourse. Vaginal dilators have also been shown to help vaginal patency in patients who are not sexually active. Vaginal dilators may be traumatic in the acute phase radiation injury, and are probably better used to address chronic vaginal problems of narrowing and shortening after inflammation has subsided (90,91). Factors such as age, smoking, hormonal status, and radiation dose influence the severity of vaginal effects, and the development of ulceration and vaginal fistulas (92). Microscopic examination of vaginal smears and vulvar/vaginal biopsies after radiation may show atypical cells that are due to radiation-induced changes. Expert pathology consultations are helpful in such instances. Care should be taken to avoid unnecessary biopsies because of the risk of ulceration.

Vulva

Acute Complications

The vulva and distal vagina are less tolerant to radiation than the proximal vagina. Maximum radiation dose to the vulva

should be limited to 70 Gy. Acute vulva changes after radiation may be observed within a month of commencing therapy. Initial effects are due to tissue injury, leading to dry desquamation. This is followed by a moist desquamation reaction that involves denudation of vulvar skin, with edema and surface vesicles due to continued acute inflammatory response (92). Daily use of sitz baths followed by drying of the vulva should be used initially for acute symptoms. Avoidance of chemical washes and friction against the vulvar skin are important.

Chronic Complications

In chronic radiation vulvitis, areas of skin may appear hypopigmented or depigmented due to loss of melanocytes. There is also loss of sebaceous glands, dermal atrophy, loss of hair, and fragility. Patients who smoke, and have chronic microvascular disease are at risk of nonhealing ulcers (92). Water-based emollients, perineal hygiene, and the avoidance of friction help to reduce dryness and sores, and prevent infection.

Ovary

Clinical effects of radiation on ovarian function are more pronounced in premenopausal patients. Acute ovarian failure occurs as a result of injury to the granulosa cells, with subsequent inability of follicle maturation. Total (fractionated) radiation dose of 24 Gy will produce permanent loss of ovarian function (93). Typical doses to the ovaries are less than this; the dose of radiation that produces lethal toxicity to 50% of ovarian follicles (LD50) has been quoted to be between 4 and 6 Gy. Wallace et al. using a model for follicle decline applied to age-related estimations of ovarian volume suggested a LD50 value of 2 Gy (Table 30.3) (94). The severity of radiation-induced ovarian failure is dependent on the age of the patient, total dose received, and concomitant use of alkylating chemotherapy. Vasomotor symptoms, as well as vaginal dryness, mood changes, diminished libido, breast atrophy, subfertility, and osteoporosis, are some of the many problems related to ovarian failure in these patients. Management is usually in accordance with established guidelines for postmenopausal symptom therapy.

Fetal Effects

Definite thresholds for fetal effects of radiation have been difficult to define in humans partly because of the species-specific nature of

Table 30.3 Predicted Mean Age of Ovarian Failure after Radiation

	3 Gy	6 Gy	9 Gy	12 Gy
Age at Treatment (years)	Ovarian Failure (years)	Ovarian Failure (years)	Ovarian Failure (years)	Ovarian Failure (years)
Birth	35.1	22.6	13.7	7.9
1	35.2	22.9	14.3	8.7
9	36.5	26.0	19.7	14.5
15	37.8	28.8	23.0	19.0
20	39.0	31.4	26.4	22.8
25	40.6	34.2	29.8	26.5
30	42.2	37.0	33.2	30.1

radiation damage. *In utero* effects of radiation are dependent on the dose received, the gestational age, the cell type, and the stage of development affected. Up to 2 weeks of gestation, radiation effects follow an “all or none” pattern (95). Therefore, either a lethal abnormality is induced in the embryonic cells, or the entire cell population of undamaged cells continues to replicate without consequences. Between 2 and 8 weeks, the most radiosensitive cells are neural cells, which undergo a process of mitosis and migration into the cerebral cortex, prior to terminal differentiation. Radiation-induced cell kill produces clinical effects of microcephaly and mental retardation in fetuses exposed to greater than 0.3 to 0.5 Gy between 8 to 15 weeks gestation. Growth retardation and microcephaly are the main effects seen between 16 and 25 weeks of high doses of radiation exposure. Severe fetal anomalies are rarely seen beyond 30 weeks gestation.

Pelvic Bone Effects

Insufficiency fractures result from diminished bone elasticity under physiologic stress conditions. External beam pelvic radiation affects bone tissue directly by reducing osteoblast number and function leading to demineralization and osteopenia. Indirect radiation effects occurs through microvascular occlusion and impaired ability of bone marrow to undergo repopulation of stem cell depleted areas. The tolerance dose of healthy bone tissue is between 65 and 70 Gy, but it is suggested that toxicity actually begins above a total dose of 45 Gy (96). Preexisting osteoporosis is the main predisposing risk factor for developing postradiation insufficiency fractures. Other factors are age and postmenopausal status, radiation dose, low body weight, smoking, chronic steroid use, diabetes, and rheumatoid arthritis. The majority of patients will develop fractures within one year of completion of treatment. Estimates of the exact incidence vary (10% to 45%) based on small retrospective studies (97). The median time to presentation is 14 months, and the sacrum may be involved in as many as 83% of patients with fractures (97). The most prevalent symptom of insufficiency fractures is pain in the sacral area of the back, and in the pubic area. The characteristic finding on radionuclide bone scans is a butterfly or H-shaped area of abnormal uptake in the sacral area (96). Most patients with insufficiency fractures respond to pelvic rest, physiotherapy rehabilitation with pelvic exercises, and nonsteroidal or opiate analgesics. Patients who receive pelvic radiation should periodically be assessed for pelvic fractures with pelvic imaging, especially when pelvic pain is reported.

Radiation osteitis results from radiation-induced microvascular injury with inflammation and ischemia. Areas of sclerosis may develop in conjunction with demineralization (96). Diagnostic confusion can occur when fractures also appear. Severe microvascular injury and osteocyte killing can lead to ischemia and an acellular bone matrix. Disruption or occlusion of the nutrient vessels and periosteal and endosteal anastomoses lead to avascular necrosis. This lesion may be seen less commonly in the femoral head.

Hematopoietic Effects

External beam pelvic radiation, especially when given with chemotherapy, commonly produces hematologic toxicity (98,99). Radiation affects hematopoietic stem cells, stromal cells, and other cells that secrete colony-stimulating factors. Acute toxicity manifests as neutropenia, anemia, and thrombocytopenia; and may be dose limiting, pending recovery of cell counts. At doses typically utilized for external beam pelvic radiation, the drop in neutrophil, platelet, and red blood cell counts reflects the kinetics and half-lives of these cells, similar to that observed with chemotherapy. Chronic radiation injury results from stromal cell damage and bone marrow fibrosis, with diminished ability of the bone marrow to support hematopoiesis.

Lymphatic Effects

Surgery or radiation alone in the pelvis or groin can lead to lymphedema, but when combined, the incidence of lymphedema increases. The prevalence of lymphedema is quoted from 11% to 18% and is greater in those treated for vulvar carcinoma with inguinofemoral lymphadenectomy and adjuvant radiation. Symptoms may be unilateral or bilateral and range from mild, soft, pitting edema to severe, indurated, brawny edema placing the woman at risk for cellulitis. Treatment includes compression stockings, massage, elevation, and good skin and nail care to avoid infection.

Neural Effects

Radiation neuropathy and plexopathy is seen most commonly between 1 and 5 years following pelvic radiation for cervical cancer. Dose threshold for this condition is not exactly known. Leg weakness, numbness, sensory changes, and leg edema are all presenting features. Loss of perineal sensation and incontinence suggest bilateral plexopathy (100). Pain is a late symptom, an important differentiating feature from tumor recurrence, which is a key differential diagnosis. Clinical evaluation helps to exclude obvious evidence of tumor. MRI is the best imaging modality for diagnosis of plexopathy. PET scan is also useful in differentiating radiation-induced plexopathy from tumor-associated plexopathy when the diagnosis is unclear. Treatment is usually supportive care with pain control.

Skin

Acute Complications

Severe skin toxicity is seen less frequently today due to the use of skin-sparing photon energy with megavoltage radiation therapy. In doses typically used for primary radiation of vulvar cancers and groin nodes, the severity of skin effects is influenced by radiation dose and type, age, preexisting medical disease, prior surgery in the radiation site, smoking, as well as overall nutritional status (101). Acute skin effects occur during treatment, and are seen for several weeks after. Direct effects on the epithelial cells of the basal epidermis, dermal capillaries, and lymphatics set up an inflammatory reaction characterized by erythema, vascular permeability, acute inflammatory cell infiltration, and release of proinflammatory molecules. Hair follicle loss and dry desquamation occur in 2 weeks, followed by plasma exudation, edema, and moist desquamation. The vulva is normally prone to moisture and friction, which can interfere with healing.

Chronic Complications

Delayed skin effects occur within 6 months. The hallmark feature is tissue hypoxia leading to atrophy of skin elements, notably sebaceous glands, sweat glands, and hair follicles (101). Compared to normal skin, there is irregular organization of elastic tissues and collagen. The skin is thin and delicate, with telangiectasias and areas of abnormal pigmentation. Doses beyond 70 Gy can lead to fibrotic, inelastic skin. Ulcers or chronic sinuses are slow or unable to heal, especially when the skin is subsequently stressed from surgery, infection, or trauma. Radiation to skin can seriously impede wound healing if surgery is required any time afterwards. Radiation is associated with decreased wound strength, with the greatest risk of breakdown during the inflammatory and proliferative phases of wound healing when fibroblasts are most active (102). The wound remodeling stage is least sensitive to the acute effects of radiation. Perineal hygiene with nonchemical washes, followed by gentle blow-drying are recommended for radiation vulvitis. Avoidance of friction and

use of cotton undergarments are helpful. The management of chronic radiation skin ulcers and fistulas is beyond the scope of this section.

MINIMIZING RADIATION-RELATED TOXICITY

A better understanding of the radiation dose and toxicity relationship over the years has led to the adoption of several measures to reduce acute and chronic effects of radiation treatments for gynecologic cancers. Strategies to help minimize normal tissue damage include treatment of all fields each day, use of a 4-field technique, 3-D conformal therapy with blocking of normal structures, shrinking-field techniques, prone position, and the use of belly boards to exclude bowel. Newer techniques such as Intensity-Modulated Radiation Therapy (IMRT) and Image-Guided Radiation Therapy (IGRT) hold promise to decrease acute and long-term toxicity. IMRT uses highly sophisticated computer software and hardware to shape the form and intensity of the radiation beam to conform more precisely to a patient's tumor and to avoid the normal tissues and is associated with a decrease in hematologic, gastrointestinal, and genitourinary side effects (103).

Over the years, many therapies have been studied as radioprotectors and sensitizers. One of the most promising is amifostine (WR-2721; Ethiol), which has noted protective effects on the salivary glands, bone marrow, oral mucosa, esophagus, intestinal mucosa, and bladder mucosa (104). The compound is an organic thiophosphate diphosphorylated to the active metabolite (WR-1065) in the tissue. The differential protection of normal versus tumor tissue is due to a differential concentration of tissue alkaline phosphatase and pH differences that allow variable metabolite uptake. After cellular uptake, WR-1065 scavenges oxygen free radicals and by this mechanism affords normal tissue radioprotection. Two randomized trials in pelvic radiation demonstrated a significant decrease in bladder and gastrointestinal toxicity without compromising median survival or therapeutic response (105,106).

COMPLICATIONS OF CHEMOTHERAPY AND BIOLOGICAL AGENTS

Chemotherapy drugs are toxins that are used to kill cancer cells. However, none of the currently available chemotherapeutic agents have toxicities that affect only the cancer cell. Most have some toxic effects on normal cells. The toxicities of chemotherapy can be categorized as acute (with onset early in treatment), or chronic (delayed or cumulative toxicities that may not appear until late in treatment or after treatment is completed).

Myelosuppression

Hematologic effects of chemotherapy affect all 3 myeloid lineages. The fall in white blood cells (WBC) starts a few days after chemotherapy and will usually nadir 10 to 14 days after chemotherapy. Severe or grade 4 neutropenia is defined as an absolute neutrophil count (ANC) less than 500/mm³; febrile neutropenia (FN) is defined as an ANC <1000/mm³ and oral temperature >38.3°C (107). FN is a major complication of chemotherapy that can require hospitalization and intravenous antibiotic treatment and may result in treatment compromise by dose reduction or delay in therapy (108). The prophylactic use of WBC colony-stimulating factors (CSFs) can reduce the

incidence and severity of FN but adds significantly to treatment cost. Most guidelines recommend prophylactic CSF use for chemotherapy regimens with a greater than 20% risk of FN (109). Gynecologic cancer regimens with a > 20% risk of FN include topotecan (daily × 5 regimen), single agent full dose docetaxel, BEP (bleomycin, etoposide, and cisplatin), MAID (mesna, doxorubicin [Adriamycin], and ifosfamide with or without dacarbazine), and gemcitabine and docetaxel (109). Of note, the taxane/carboplatin combination regimens have a lower risk of FN and routine prophylactic CSF use is not recommended for these regimens (110). In addition to the specific chemotherapy regimen used, age over 60, prior FN, and prior exposure to multiagent chemotherapy increase risk of FN and may be indications for prophylactic CSF.

The effects of chemotherapy on platelets may manifest later with nadirs as late as days 14 to 18 of a 21-day cycle. Carboplatin in particular has a potent effect on the platelets. Carboplatin-related thrombocytopenia is frequently cumulative such that nadir platelets decline with continued treatment. The gradual onset of thrombocytopenia allows for dose and schedule modification; as a result, severe thrombocytopenia is rare (111).

Red blood cells have a much longer half-life than platelets or WBCs so anemia may manifest much later in treatment. Patients who have significant blood loss with initial surgery are clearly at greater risk for chemotherapy-related anemia. Erythropoietin-stimulating agents (ESAs) have been associated with decreased survival and should be used only during chemotherapy for symptomatic patients with hemoglobin less than 11 g/dL or asymptomatic patients with hemoglobin less than 10 g/dL who are at risk for symptomatic anemia (112).

Emesis

Chemotherapy-related nausea and vomiting is largely a central nervous system effect related to stimulation of the chemoreceptor trigger zone. Poorly controlled nausea leads to metabolic abnormalities, poor treatment compliance, and anticipatory nausea. The incidence of emesis is affected by the agent, the dose, and the schedule. Acute nausea peaks 4 to 6 hours after chemotherapy and usually resolves within 24 hours of treatment. Delayed nausea, occurring more than 24 hours after chemotherapy, is most commonly seen with cisplatin and adriamycin. Cisplatin-associated emesis peaks 2 to 3 days after chemotherapy, but can last up to 7 days. Prophylactic treatment is based on the emetogenic potential of the treatment regimen and should be initiated before chemotherapy. 5-HT₃-receptor antagonists have provided a significant advance in control of nausea and emesis. Dexamethasone improves the efficacy of 5-HT₃-receptor antagonists. Neurokinin-1 receptor antagonist therapy blocks the binding of substance P to NK-1 receptors and adds additionally to 5-HT₃-receptor antagonists and dexamethasone. Multiday regimens such as BEP or MAID are particular challenges and require close monitoring of nausea and emesis (113).

Nephrotoxicity

Cisplatin is the chemotherapeutic agent most commonly associated with renal compromise. Cisplatin produces its nephrotoxic effects by damaging the renal tubules, resulting in a decrease in the glomerular filtration rate (114). Vigorous isotonic saline hydration to maintain a urine output of at least 100 mL/hour decreases the concentration of cisplatin at the tubules and significantly reduces the risk of renal toxicity from cisplatin. A common regimen will be 1 L of normal saline supplemented with potassium and magnesium over 2 to 3 hours before cisplatin and 500 mL of the same solution over 2 hours after cisplatin. Forced diuresis with mannitol to maintain urine output can lead to transient intravascular dehydration and exacerbate cisplatin

nephrotoxicity (115). Likewise, furosemide should not be used unless there is evidence of volume overload. Cisplatin nephrotoxicity is cumulative; thus, close monitoring of creatinine is mandatory. Even rises that remain within normal limits can indicate a significant decrease in creatinine clearance. In addition, the use of other nephrotoxic agents, such as IV contrast, should be avoided near the time of cisplatin administration.

In addition to abnormalities in renal function tests, electrolyte abnormalities such as hypomagnesemia, hypocalcemia, and hypokalemia resulting from defective distal tubular reabsorption can be seen after cisplatin administration. This can be a long lasting effect and some patients require electrolyte monitoring for years after cisplatin use.

Neurotoxicity

A major dose-limiting side effect of cisplatin is neurotoxicity. The common neurologic effects of cisplatin include peripheral sensory neuropathy and ototoxicity; however, retinal toxicity, encephalopathy, seizures, and autonomic dysfunction can also occur. Cisplatin predominantly affects large sensory fibers. Typical symptoms are numbness, paresthesias, and pain beginning in the fingers and toes. This can progress proximally in a “stocking glove” distribution and can ultimately result in difficulty in walking and impaired fine motor functions such as writing, typing, and buttoning. Physical exam findings will include loss of deep tendon reflexes, decreased vibratory sensation, and diminished proprioception (116). Although cisplatin-induced neurotoxicity may occur after a single dose, it more commonly increases with higher cumulative doses.

Cisplatin may also cause tinnitus and hearing loss in the high frequency range in a dose-dependent fashion (117). High-dose cisplatin regimens of 100 mg/m² per dose or higher achieve very high peak plasma levels that appear to result in a greater incidence of ototoxicity than lower-dose regimens.

The antitumor effect of paclitaxel (Taxol) results from promoting microtubule assembly. As a consequence, neuropathy is one of its toxic side effects. Some patients treated with paclitaxel report an acute painful musculoskeletal toxicity with arthralgias and myalgias that usually peak in the first 5 days after treatment. It is not clear whether this is a neurologic toxicity, but it is frequently classified as such. This can usually be managed with nonsteroidal medications, but sometimes requires the use of narcotic analgesics. A cumulative peripheral sensory neuropathy is the most commonly reported neurotoxic effect of paclitaxel. Symptoms include symmetrical numbness, paresthesias, and burning pain in a glove-and-stocking distribution.

The combination of paclitaxel and cisplatin has been shown to have the potential to produce a higher incidence of peripheral neuropathy than either agent used alone. Of particular concern is the combination of cisplatin (75 mg/m²) and short duration, 3-hour infusion of paclitaxel (175 mg/m²) administered on the same day. Studies demonstrate a 20% to 25% incidence of severe (grade 3) peripheral neuropathy using cisplatin with short infusion paclitaxel (118). For this reason, IV cisplatin is commonly given after a prolonged, 24-hour infusion of paclitaxel. An alternative is to administer cisplatin on day 2, one day after 3-hour paclitaxel; however, the incidence of neurotoxicity with this approach has not yet been well documented.

Although less neurotoxic than cisplatin plus paclitaxel, combination chemotherapy with carboplatin and paclitaxel, a commonly employed regimen in several gynecologic malignancies, also has the potential to produce peripheral neuropathy (119).

Pulmonary Toxicity

Bleomycin, an antitumor antibiotic, is a component of the BEP treatment regimen used for malignant germ cell tumors.

The most serious toxic effect of bleomycin is a potentially life-threatening interstitial pulmonary fibrosis that can occur in up to 10% of patients (120). The mechanism of bleomycin-induced lung injury is not entirely clear but oxidative damage to the lung appears important. The toxicity is rare (0% to 2%) in patients who have received a total cumulative bleomycin dose <270 mg but increase to 6% to 18% when dose reaches 360 mg (121). However, it should be noted that severe pulmonary toxicity has been observed at total bleomycin doses <100 mg. In addition to the cumulative dose received, other risk factors for bleomycin-induced pulmonary dysfunction include age >40 years and prior or concurrent thoracic irradiation.

Patients who are to receive bleomycin should have screening pulmonary function testing, including carbon monoxide-diffusing capacity (DLCO). These should be repeated if the patient develops cough, dyspnea, crackles on lung exam, or abnormal chest imaging. Mild worsening of DLCO (15% to 20%) is common in bleomycin-treated patients. A more substantial worsening, particularly in combination with new symptoms, should lead to discontinuation of bleomycin. Corticosteroid therapy is the mainstay of treatment, but has little or no impact on established fibrotic lesions.

Cardiac

Doxorubicin has demonstrated activity in several gynecologic malignancies and is a component of a number of commonly used treatment regimens. Doxorubicin has a serious potential side effect of cumulative cardiac toxicity when given as a bolus administration (122). Cardiac abnormalities are rarely observed with a total doxorubicin dose <350 mg. With a cumulative dose of >550 mg/m², the incidence of cardiac dysfunction is 1% to 10%. Doxorubicin-induced heart injury is unique, and specific histologic features, best seen on electron microscopy, can be observed in tissue obtained through an endomyocardial biopsy during a right-heart catheterization (123).

Risk factors for cardiac toxicity include a history of significant hypertension, preexisting cardiac disease, prior cardiac or mediastinal irradiation, and age >70 years (124). Evaluation of left ventricular ejection fraction (LVEF) with MUGA or ECHO is recommended before initiating doxorubicin treatment for anyone with any of the above risk factors. Most clinicians additionally evaluate LVEF in patients over age 50 to rule out occult, unexpected cardiac function abnormalities. Some advocate LVEF evaluation in any patient who will receive doxorubicin. LVEF should be reevaluated after a cumulative doxorubicin dose of 250 to 300 mg/kg. In most patients, a major drop in the cardiac ejection fraction is observed *before* the onset of clinical symptoms, allowing for discontinuation of doxorubicin before more serious damage results.

It should be noted that administration of doxorubicin by continuous infusion (as in the MAID regimen) or by sustained release (if liposomal form) does not have the same cardiac toxicity as bolus administration (125).

The rate of doxorubicin cardiac toxicity is increased when it is administered with paclitaxel or with the anti-HER2/ neu monoclonal antibody trastuzumab (Herceptin). In the TAP regimen (paclitaxel [taxol], doxorubicin [Adriamycin], and cisplatin) used for treatment of endometrial cancer paclitaxel and cisplatin are given on day 1 and doxorubicin is given on day 2. The incidence of grade 3 or greater congestive heart failure was 2% with that regimen (126).

Infertility

Improvements in early diagnosis and treatment have resulted in improved survival rates of women with cancer. However, chemotherapy has clear gonadal toxicity resulting in premature

amenorrhea and frank ovarian failure. When premenopausal women are diagnosed with cancer, concerns about preserving fertility may seem secondary to optimizing treatment outcomes. But for many women, optimizing fertility preservation represents hope for the future and a desire to reclaim their “normal” life. Women who have deferred childbearing until late in life often see maintaining fertility as a means of not allowing cancer to derail their life goals (127).

The ovary is especially susceptible to chemotherapy because of the normal decline in the number of primordial follicles after birth and the inability of follicles to replicate. The overall risk of infertility depends on several factors, including the chemotherapy drugs used, the intensity of the drugs, the duration of treatment, the age of the patient, and her existing ovarian reserve. Chemotherapy primarily affects the replicating, hormone-producing granulosa and theca cells but has little direct effects on the quiescent oocytes (128). The chemotherapy drugs most strongly associated with ovarian damage are the alkylating agents, such as cyclophosphamide, and anthracycline doxorubicin. Cisplatin and etoposide are less toxic to the ovary, while the gonadal toxicity of bleomycin and taxanes are unknown. Follicular damage leads to decreased ovarian hormone production, elevated gonadotropins, and greater follicular recruitment. This positive feedback loop results in an accelerated rate of damage with more prolonged therapy. Thus, duration of treatment impacts ovarian reserve and the fewer ovulatory cycles of exposure, and there is less ensuing follicular damage (128).

Chemotherapy-associated amenorrhea should not necessarily be equated with loss of fertility. Amenorrhea may be transient and many women will have return of menses and maintain fertility.

The risk of infertility and possible pretreatment interventions should be discussed with women who desire fertility preservation before chemotherapy is started. Embryo cryopreservation is the best-established technique for preserving reproductive capacity (129). This requires ovarian stimulation and oocyte retrieval, which can take 2 to 6 weeks. Thus, embryo cryopreservation should be attempted only when there is no contraindication to use of the hormones required for ovarian stimulation and when chemotherapy can be safely deferred. This also requires an available partner or donor as a sperm source. Cryopreservation of oocytes or ovarian tissue remains investigational at this time (130). Women who have stored embryos but who develop amenorrhea during chemotherapy will require exogenous estrogen and progesterone to prepare the endometrium for implantation. This hormonal therapy will need to continue at least through the first trimester until the placenta is able to provide the necessary hormonal support.

The use of GnRH agonists to protect ovarian function during chemotherapy remains controversial. While some studies have demonstrated improved rates of resumption of menstruation after GnRH use, improved pregnancy outcomes have not yet been demonstrated (131).

Secondary Hematologic Malignancies

The administration of DNA-damaging chemotherapy has been associated with an increase in the risk of developing acute myelogenous leukemia (AML) and myelodysplastic syndrome (MDS). Alkylating agents in particular have been most strongly associated with secondary leukemias, but topoisomerase inhibitors and platinum agents are also implicated. The peak incidence of secondary leukemia occurs 4 to 5 years after alkylating agent administration, while the latency for topoisomerase-inhibitor associated leukemia is shorter, approximately 18 months. Secondary hematologic malignancies have an especially poor prognosis with survival that is significantly inferior to *de novo* AML (132).

Current chemotherapy for EOC has changed significantly over the past 2 decades. In particular, the alkylating agents have been largely replaced with taxanes. Vay and colleagues recently reported on changing patterns of AML after a diagnosis of EOC using the NCI Surveillance, Epidemiology, and End Results (SEER) database from 1973 through 2006 (133). They identified 199 AML cases among 63,359 patients with a prior diagnosis of EOC, an overall incidence of 0.17%, and found that the median latency to development of leukemia was 4 years after diagnosis, a time consistent with prior observations of alkylating agent-associated secondary leukemias (134). They found that secondary leukemia rates have significantly decreased with more recent EOC diagnosis. The incidence of secondary leukemia was 6/1000 in those diagnosed before 1982, 2/1000 for patients diagnosed between 1982 and 1996, and 0.4/1000 for EOC diagnosed after 1996. These time periods reflect major shifts in EOC treatment. In 1982, platinum-based chemotherapy became the standard of care, and in 1996, paclitaxel replaced cyclophosphamide in EOC treatment regimens. This is an overall 15-fold lowering of the secondary leukemia incidence during the time period under study. It is, however, recognized that some aspects of contemporary EOC treatments have the potential to increase DNA damage and contribute to second malignancies including more prolonged therapy with maintenance and consolidation, the use of targeted therapies, particularly PARP inhibitors, the use of colony stimulating WBC growth factors, and radiographic imaging used to follow disease (134–136).

■ PAULINE LESAGE

The heterogeneous patient population managed by gynecologic oncologists presents a broad range of problems in pain management. The incidence of cancer pain varies, depending on the type of neoplasm, stage, and extent of spread. Acute pains are highly prevalent, including the rather straightforward incisional pain that follows surgical procedures. Chronic pain occurs in the context of numerous other physical and psychosocial symptoms, often in the population with advanced disease. Effective relief of pain may improve mood, coping, function, and other aspects of quality of life. Gynecologic oncologists have the opportunity and obligation to effectively treat pain.

SCOPE OF THE PROBLEM

Pain is highly prevalent in the cancer population. Overall, 30% to 50% of patients undergoing active antineoplastic therapy and 75% to 90% of those with advanced disease experience chronic pain severe enough to warrant therapy (1–3). Although data specific to gynecologic tumors are meager, those extant suggest that the overall prevalence rates mirror these averages (1,4–6).

A survey of patients with ovarian cancer illustrates the prevalence and characteristics of chronic pain in this population (6). The sample included 111 inpatients and 40 outpatients. The median age was 55 years (range, 23 to 86 years), and most patients (82%) had stage III or IV disease at presentation and active disease (69%) at the time of the survey. Forty-two percent (n = 63) reported “persistent or frequent pain” during the preceding 2 weeks. This pain had a median duration of 2 weeks (range, <1 to 756 weeks) and was usually abdominal/pelvic (80%), frequent or almost constant (66%), and moderate to severe. Most patients reported that pain caused moderate or greater interference with various aspects of function, particularly activity (68%), mood (62%), work (62%), and overall enjoyment of life (61%). In a study of 97 outpatients with breast cancer (54% metastatic disease), 47% of patients experienced cancer-related pain substantially interfering with their mood, quality of life, and functional status. The most prevalent underlying pathology was postmastectomy syndrome (56%), followed by pain from bone metastasis (26%).

Tissue injury related to the neoplasm itself is the most common cause of chronic cancer pain. Pain prevalence increases with the extent of disease and can be as high as 90% among populations with advanced illness (7). Chronic pain also may be related to an antineoplastic treatment, such as surgery (8–10), and in a small minority of patients, pain is unrelated to either the malignancy or its treatment.

Observational studies suggest that satisfactory relief of chronic pain is possible in 70% to 90% of patients with cancer

(11–14). However, undertreatment remains a serious problem, however (15–19), despite the availability of well-accepted guidelines for pain management (20). It has been suggested that an average of 43% of cancer patients receive inappropriate care for pain (21). Many concerns may undermine optimal treatment, among which are the underreporting of symptoms or nonadherence of patients, and the inadequate assessment, knowledge, or communication of health professionals (22).

Although the prevalence of severe acute pain in patients with gynecologic cancers has not been determined, and is likely changing with the increasing use of minimally invasive procedures, it is nonetheless presumed to be common and potentially controllable in a very large majority of cases. As more cancer surgeries are performed in the ambulatory setting, the ability to provide adequate treatment in unmonitored settings has become a greater challenge.

Patients with cancer, particularly those with advanced disease, also experience numerous symptoms other than pain. The most common of these symptoms are fatigue and anxiety or depression. Acute treatment-related symptoms, such as chemotherapy-induced nausea and vomiting, also are prevalent. In the aforementioned survey of patients with ovarian cancer, the median number of symptoms per patient was 9 (range, 0 to 25) (Table 31.1) (6). In addition to pain, the most prevalent symptoms were fatigue (“lack of energy”), psychologic distress (“worrying,” “feeling sad,” and “feeling nervous”), and insomnia (“difficulty sleeping”). All of these symptoms had a prevalence of greater than 50%. Compared to norms, approximately one-third of the patients in this survey recorded heightened psychologic distress. The most important predictor of heightened distress was progressive impairment in physical functioning. Distress also can be worsened by psychological or social factors, or by spiritual or existential challenges (21).

Fatigue is one of the most common complications of cancer and its treatment, and exemplifies the problem of concurrent symptoms in the patient with significant pain. In a recent analysis, patients perceived fatigue to be the most distressing symptom adversely affecting quality of life (23). A definition proposed for the International Classification of Diseases 10th Revision–Clinical Modification (ICD-10-CM) stresses the multidimensional nature of the phenomenon (24) and the National Comprehensive Cancer Network 2011 guidelines identified 8 factors that should be assessed as potential causes of prolonged fatigue, one of which is pain (others include medications/side effects, emotional distress, sleep disturbance, anemia, nutrition, decreased functional status, and other comorbidities) (25). Patients with pain should be evaluated for meaningful concomitant symptoms, and the assessment of other symptoms should prompt an assessment of pain.

Table 31.1 Prevalence and Characteristics of Symptoms Associated with Ovarian Cancer (n = 151)

Symptom	Overall Prevalence (%)	Intensity ^a (%)	Frequency ^b (%)	Distress ^c (%)
Worrying	71.7	55.4	33.5	25.0
Lack of energy	68.6	52.6	37.3	28.0
Feeling sad	63.8	46.4	22.8	22.2
Pain	61.8	50.4	32.9	24.1
Feeling nervous	61.5	39.9	25.0	19.6
Difficulty sleeping	57.3	44.0	30.7	20.7
Dry mouth	45.6	30.2	18.8	8.7
Feeling drowsy	45.3	32.7	15.9	9.3
Feeling irritable	45.9	33.8	12.2	10.8
Numbness/tingling in hands/feet	42.7	24.0	26.0	9.3
“I don’t look like myself”	35.8	25.0	—	12.8
Nausea	35.6	18.8	9.4	8.1
Difficulty concentrating	34.7	16.0	7.3	11.3
Feeling bloated	34.7	26.0	17.3	8.7
Constipation	28.6	20.4	—	11.6
Lack of appetite	28.4	20.4	14.2	8.2
Change in the way food tastes	25.7	16.2	—	8.1
Hair loss	26.4	15.0	—	9.5
Cough	25.3	11.3	6.0	4.0
Itching	22.3	11.5	8.1	3.4
Diarrhea	20.8	10.1	6.0	4.0
Swelling of arms or legs	18.9	12.2	—	8.8
Shortness of breath	18.7	10.0	7.3	6.0
Weight loss	18.5	4.8	—	3.4
Problems with sexual interest or activity	17.6	14.9	10.9	6.8
Dizziness	16.2	5.4	2.7	2.7
Vomiting	13.3	8.7	3.3	6.0
Mouth sores	8.1	4.7	1.4	2.0
Nightmares	8.0	5.3	2.0	2.0
Problems with urination	7.3	5.3	4.0	3.3
Urinary accidents	7.4	4.1	0.7	1.4
Difficulty swallowing	5.4	3.4	2.7	2.0

^aPercentage of sample describing the symptom as “moderate,” “severe,” or “very severe.”

^bPercentage of sample describing the frequency of the symptom as “frequently” or “almost constantly.”

^cPercentage of sample describing the distress associated with the symptom as “quite a bit” or “very much.”

ASSESSMENT OF CANCER PAIN

The assessment of chronic pain in patients with gynecologic cancer requires an understanding of its phenomenology, pathophysiology, and syndromes. Optimally, this assessment must also consider the broad range of physical, psychologic, and social disturbances concurrently experienced by these patients. Patients with acute pain, particularly acute postoperative pain, pose less complex management problems, but could still potentially benefit from an ongoing comprehensive assessment. The patient's description of the pain, findings on physical examination, objective data from imaging and other tests, and information about the extent of the malignant disease and its treatment are all utilized to assess the likely etiology and underlying pathophysiology of the pain, and if possible, identify a specific cancer syndrome (26).

National medical organizations have developed guidelines in an effort to more effectively detect and monitor pain. The Joint Commission on Accreditation of Healthcare Organizations developed a standard requiring that pain be assessed initially and periodically in all hospitalized patients. The National Comprehensive Cancer Network 2011 Adult Cancer Pain Guidelines require a formal pain assessment, measurement of pain intensity, reassessment of pain intensity at specific intervals, psychosocial support, and specific educational material (25).

Definition of Pain

According to the International Association for the Study of Pain, pain is "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (27). Reported pain may be perceived by the clinician to be greater than or less than the observable degree of tissue injury. In the cancer population, a physical process capable of explaining the pain can usually be identified, but this does not obviate the need for a careful assessment of other factors, including psychologic disturbances, that could be influencing the intensity of the pain or contributing to pain-related distress.

The definition of pain can be further clarified by the distinctions among nociception, pain, and suffering (Fig. 31.1) (28). Nociception is the activity produced in the afferent nervous system by potentially tissue-damaging stimuli. Clinically, nociception is inferred to exist whenever tissue damage is identified. Pain is the perception of nociception and, like other perceptions, can be determined by more than the activity in the sensorineural apparatus alone. Although tissue damage related to the tumor or its treatment is common in those with cancer pain, a careful assessment is needed to infer the degree to which the pain report is consistent with the nociception presumed by the clinician on

FIGURE 31.1. Distinctions and interactions between nociception, pain, and suffering.

Source: Reproduced with permission from Portenoy RK. Cancer pain: pathophysiology and syndromes. *Lancet*. 1992;339:1026–1031.

the basis of the physical findings. In all cases, factors other than nociception, including neuropathic processes that can sustain pain in the absence of ongoing tissue injury (see below) and psychologic disturbances, must be evaluated as other potential determinants of the pain. The failure to address these other factors while targeting therapy at the sources of nociception can lead to a poor outcome in which the focus of tissue damage is ameliorated but the pain continues.

Suffering, or "total pain," can be defined as a more global aversive experience determined by numerous perceptions, one of which may be pain (see below). Among the many other factors that may contribute to suffering are the perception of physical deterioration, the experience of symptoms other than pain, psychologic disturbances (e.g., depression or anxiety), disruption in the family, social isolation, and fear of death. Just as an inordinate focus on nociception, rather than pain, can lead to interventions that reduce tissue damage without alleviating symptoms, an emphasis on pain management alone in patients with profound suffering determined by other factors can fail to influence favorably the overall quality of life even if physical comfort is enhanced (29,30).

Evaluation of the Pain Complaint

The comprehensive assessment of pain should include information about temporal characteristics (onset and duration), course (stable or changing since onset, relatively constant or widely fluctuating), severity (both average and worst), location, quality, and provocative and palliative factors. This evaluation is complemented by information about the patient's extent of disease, related medical and psychosocial conditions, present and past pain management strategies and their outcomes, the impact of the pain on the patient's daily life and functioning, as well as the patient's and family's knowledge of, expectations about, and goals for pain management. Risk factors for the undertreatment of the patient's cancer pain and risk factors for serious physical or psychiatric comorbidities (such as drug abuse) should also be examined.

Characteristics of Pain

Intensity. The measurement and recording of pain intensity is an essential element in the comprehensive assessment of pain. Although more information than intensity alone is needed to understand and manage cancer pain, a systematic method for assessing intensity is foundational. The most common approaches are a verbal rating scale (none, mild, moderate, severe, excruciating) and/or an 11-point numeric scale (where 0 is no pain and 10 is the worst pain imaginable). A visual analog scale (VAS) that uses a 10-cm line anchored at one end by the words "no pain" or "least possible pain" and at the other end by "worst possible pain" is another simple and valid approach to pain measurement. The choice of scale is less important than consistency in its use over time. Brief assessment tools modeled on this approach also can be applied to the intensity measurement of nonpain symptoms, such as depression and fatigue.

Multidimensional scales are available, but usually are utilized in research settings. These scales provide a more comprehensive measure of the pain experience, often encompassing such factors as function and quality of life.

Temporal. Acute pain usually has a well-defined onset and a readily identifiable cause (e.g., surgical incision). It may be associated with anxiety, overt pain behaviors (moaning or grunting), and signs of sympathetic hyperactivity (including tachycardia, hypertension, and diaphoresis). In contrast, chronic pain is characterized by an ill-defined onset and a prolonged, fluctuating course. Overt pain behaviors and sympathetic

hyperactivity are typically absent, and vegetative signs, including lassitude, sleep disturbance, and anorexia, may be present. A clinical depression evolves in some patients. Most patients with chronic cancer pain also experience periodic flares of pain, or “breakthrough pain,” an observation with important therapeutic implications (see below).

Topographic. The distinctions among focal, multifocal, and generalized pains may influence both the assessment and treatment of the patient. Some therapies, such as nerve blocks and cordotomy, depend on the specific location and extent of the pain.

The distinction between focal and referred pain is similarly important. Focal pains are experienced superficial to the underlying nociceptive lesion, whereas referred pains are experienced at a site distant from the nociceptive lesion.

Pain may be referred from a lesion involving any of a large group of structures, including nerve, bone, muscle, or other soft tissue, and viscera (31–33). Various subtypes can be distinguished: (a) pain referred anywhere along the course of an injured peripheral nerve (such as pain in the thigh or knee from a lumbar plexus lesion); (b) pain referred along a course of the nerve supplied by a damaged nerve root (known as radicular pain); (c) pain referred to the lower part of the body, usually the feet and legs, from a lesion involving the spinal cord (called funicular pain); and (d) pain referred to a site remote from the nociceptive lesion and outside the dermatome affected by the lesion (e.g., shoulder pain from diaphragmatic irritation). Knowledge of pain referral patterns is needed in order to target appropriate assessment procedures. For example, a patient with recurrent cervical cancer who reports progressive pain in the inguinal region may require evaluation of numerous structures to identify the underlying nociceptive lesion, including the subjacent pelvic bones and hip joint, pelvic sidewall, paraspinal gutter at an upper lumbar spinal level, and intraspinal region at the upper lumbar level.

Etiology

The etiology of acute pain is usually clear-cut. Further evaluation to determine the underlying lesion or pathophysiology of the pain is not indicated unless the course varies from the expected. In contrast, the etiology of chronic cancer-related pain may be more difficult to characterize. In most cases, pain is due to direct invasion of pain-sensitive structures by the neoplasm (27,28,34). The structures most often involved are bone and neural tissue, but pain can also occur when there is an obstruction of hollow viscus, distention of organ capsules, distortion, or occlusion of blood vessels, and infiltration of soft tissues. The etiology of pain in less than a quarter of patients relates to an antineoplastic treatment, and less than 10% have pain unrelated to the neoplasm or its treatment (34).

These data suggest that a careful evaluation of cancer patients with pain is likely to identify an underlying nociceptive lesion, which will usually be neoplastic. A survey of patients referred to a pain service in a major cancer hospital noted that previously unsuspected lesions were identified in 63% of patients (35). This outcome altered the known extent of disease in virtually all patients, changed the prognosis for some, and provided an opportunity for a primary antineoplastic therapy in approximately 15%.

Pathophysiology

Pain is labeled nociceptive if it is inferred that the sustaining mechanisms involve ongoing tissue injury. This injury can involve either somatic or visceral structures. The quality of somatic nociceptive pain is typically described as aching, stabbing,

throbbing, or pressure-like. The quality of visceral nociceptive pain is largely determined by the structures involved. Obstruction of hollow viscus is usually associated with complaints of gnawing or crampy pain, whereas injury to organ capsules or mesentery is associated with an aching or stabbing discomfort.

Pain is labeled neuropathic if the evaluation suggests that it is sustained by abnormal somatosensory processing in the peripheral or the central nervous system (CNS) and there is some identifiable neurologic injury. Neuropathic mechanisms are involved in approximately 40% of cancer pain syndromes and can be disease-related (e.g., tumor invasion of nerve plexus) or treatment-related (e.g., postmastectomy syndrome, chemotherapy-induced painful polyneuropathy) (34). Among those with metastatic disease, neuropathic pain usually results from neoplastic injury to peripheral nerves. Other, less common subtypes include (a) those in which the focus of activity is in the CNS (sometimes generically termed deafferentation pain); and (b) those in which the pain is believed to be maintained by efferent activity in the sympathetic nervous system (so-called sympathetically maintained pain). Identification of a neuropathic mechanism is extremely important in clinical management because specific therapies may be useful for these conditions (see below).

Neuropathic pain is diagnosed on the basis of the patient's verbal description of the pain and evidence of injury to neural tissue. Patients may use any of a variety of verbal descriptors but some, such as “burning,” “shock-like,” or “electrical,” are particularly suggestive of neuropathic pain (36,37). Areas of abnormal sensations are often found on physical examination. These may include hypesthesia (a numbness or lessening of feeling), paresthesias (abnormal nonpainful sensations such as tingling, cold, or itching), hyperalgesia (increased perception of painful stimuli), hyperpathia (exaggerated pain response), and allodynia (pain induced by nonpainful stimuli such as a light touch or cool air).

Although pain can occur as a primary outcome of psychologic processes, labeled in psychiatric parlance as one of the somatoform disorders, this appears to be rare in the cancer population. Nonetheless, psychologic factors may augment or alter the pain complaint, and not surprisingly, pain may be associated with fluctuations in psychologic distress. In one series of 203 inpatients with cancer, for example, depression was independently associated with pain intensity after controlling for performance status, disease status, and perceived treatment effect (38).

To assess the complex relationship between pain and psychiatric disease, it is useful to have familiarity with the common disorders that are present in gynecologic malignancies. One study observed major depression in nearly one quarter of women hospitalized with cervical, endometrial, and vaginal cancer (39), and another reported more severe depression and poorer body image among gynecologic patients than those with breast cancer undergoing mastectomy (40).

If the assessment of the pain does not provide enough information to categorize it as primarily nociceptive or neuropathic, or mixed, or yield a sufficient understanding of the psychologic factors that may be influencing the pain, it is important to acknowledge this lack of certainty and avoid labeling the patient with a term that may inappropriately direct care. The greatest concern in this regard is the labeling of pain as psychogenic when the assessment does not yield positive evidence of a psychiatric disorder, but an alternative answer is lacking. In this case, it is better to label the pain idiopathic than to speculate about underlying factors that are not clearly demonstrable from the evaluation.

Pain Syndromes

Efforts to improve the assessment of cancer pain have been greatly encouraged by the description of numerous pain

syndromes, each of which is defined by a cluster of symptoms and signs (Table 31.2) (27,28,34,41,42). Syndrome identification can help direct the diagnostic evaluation, clarify the prognosis, and target therapeutic interventions. Recognition of pain syndromes that occur commonly among patients with gynecologic cancers (Table 31.3) can also facilitate the assessment of these patients.

Table 31.2 Cancer Pain Syndromes

- I. Pain associated with direct tumor involvement
 - A. Due to invasion of bone
 1. Base of skull
 2. Vertebral body
 3. Generalized bone pain
 - B. Due to invasion of nerves
 1. Peripheral nerve syndromes
 2. Painful polyneuropathy
 3. Brachial, lumbar, sacral plexopathies
 4. Leptomeningeal metastases
 5. Epidural spinal cord compression
 - C. Due to invasion of viscera
 - D. Due to invasion of blood vessels
 - E. Due to invasion of mucous membranes
- II. Pain associated with cancer therapy
 - A. Postoperative pain syndromes
 1. Postthoracotomy syndrome
 2. Postmastectomy syndrome
 3. Postradical neck dissection
 4. Postamputation syndromes
 - B. Postchemotherapy pain syndromes
 1. Painful polyneuropathy
 2. Aseptic necrosis of bone
 3. Steroid pseudorheumatism
 4. Mucositis
 - C. Postirradiation pain syndromes
 1. Radiation fibrosis of brachial or lumbosacral plexus
 2. Radiation myelopathy
 3. Radiation-induced peripheral nerve tumors
 4. Mucositis
- III. Pain indirectly related or unrelated to cancer
 - A. Myofascial pains
 - B. Postherpetic neuralgia
 - C. Chronic headache syndromes

Table 31.3 Pain Syndromes Commonly Encountered among Patients with Gynecologic Cancer

Acute Pain Syndromes

At any stage of disease:

Postoperative pain

Mucositis

In advanced stages of disease:

Recurrent bowel obstruction

Ureteral obstruction

Movement-related pain in brachial/lumbosacral plexopathy

Movement-related pain from bony lesions

Cancer-Related Chronic Pain Syndromes

Brachial/lumbosacral plexopathy

Chronic abdominal pain: bowel obstruction, ascites, hepatomegaly

Tenesmoid pain

Bone pain from metastases

Treatment-Related Chronic Pain Syndromes

Postmastectomy syndrome

Radiation-induced plexopathy

Chemotherapy-induced peripheral neuropathy (paclitaxel, cisplatin)

Comprehensive Assessment

A comprehensive assessment that incorporates this pain-related information can be used to elaborate a problem list that guides the priorities and direction of therapy. In many situations, such as acute postoperative pain or chronic pain related to a well-characterized lesion (e.g., pathologic fracture), the assessment issues are simple and the problem list is brief and straightforward. In other cases, most often in populations with advanced disease, a complex group of symptoms, medical disorders, and psychosocial disturbances greatly complicate the assessment process. In these cases, a comprehensive assessment encourages efficient selection of an appropriate multimodal therapy.

The biopsychosocial model implied by this clinical reality has provided a framework for pain research. A consensus has been reached that the core outcome domains for studies of chronic pain are pain intensity, physical functioning, emotional functioning, participant ratings of improvement and satisfaction with treatment, and other symptoms and adverse events (43).

Patients whose pain had been responsive to pain medication but experience an increase in pain intensity or a change in pain characteristics should be comprehensively reassessed as the initial step in management. The goal is to determine whether specific factors responsible for the change can be identified. Relapse or disease progression, for example, may be amenable to primary therapeutic strategies, such as chemotherapy to address disease progression associated with loss of analgesic effectiveness. Other factors, such as cord compression, systemic or local infection, and psychological distress (e.g., depression), also may be treatable.

MANAGEMENT OF ACUTE PAIN

Although the treatment of patients with acute pain, particularly postoperative pain, is typically less challenging than the long-term management of chronic pain, the outcomes achieved in routine practice settings are often inadequate. Given the potential efficacy of widely used strategies, such as patient-controlled analgesia (PCA), less-than-satisfactory outcomes may be more related to systems issues, such as access to a pain service or prolonged pharmacy preparation times, than purely clinical issues. Cancer patients also commonly have concurrent medical problems, psychologic disturbances, and prior and current drug exposures that may increase the heterogeneity of the population and diminish the likelihood that routine measures provide adequate relief of pain. The need for clinicians and administrators to attend to the problem of acute pain and provide the resources and systems for expert management is therefore particularly important in this population.

“Routine” Approach to Postoperative Pain

Despite great variability in the pharmacokinetics and pharmacodynamics of single opioid doses (44), and the large proportion of patients who fail to attain adequate analgesia with routine postoperative care, many patients do respond adequately to an opioid, traditionally morphine or meperidine, administered “as needed.” In the cancer population, the starting dose must take into account the prior opioid exposure of the patient. A reasonable starting dose for morphine in opioid-naïve patients, for example, would be 5 to 8 mg every 3 hours as needed, or 1 mg every 6 minutes as needed if a PCA device is used. If the patient has a history of current opioid use for pain, a reasonable starting dose would be the equivalent of 5% to 10% of the total opioid consumption during the previous 24 hours. If the drug or route of administration is changed, an equianalgesic dose table must be consulted to calculate the equivalent total daily dose of the new drug. Once a dose is selected, it can be initially administered every 3 hours as needed. If repetitive dosing is employed, and the dose or interval selected initially is not effective after the first or second dose, an increase in the dose or shortening of the dosing interval should be considered.

As-needed dosing of this type usually is most effective when a procedure is likely to yield pain for a short while. In these cases, the use of an opioid with a short half-life, such as morphine or hydromorphone is preferred; meperidine, although likely to be well tolerated during brief therapy, is generally not preferred because of the availability of safer drugs (see below). The use of the intravenous route through slow injection or brief infusion will reduce distress associated with painful injections.

The proportion of cancer patients with postoperative pain who will be undertreated by an as-needed dosing schedule can be diminished if several factors are recognized. Most important, titration may be needed. The variability in analgesic requirements may require changes in the starting dose, adjustment in the dosing interval during the immediate postoperative period, or both. Some patients require several dose adjustments. Similarly, variability in pain duration after any particular operation is great and the duration of opioid treatment must be flexible and be determined solely by patient response. Some patients have concerns about opioid-induced side effects and addiction, which may augment distress and diminish patient compliance with therapy unless strong reassurance is provided by the physician and other staff.

In some populations, the routine approach to postoperative pain management can be enhanced by the use of a nonopioid

analgesic, specifically a nonsteroidal anti-inflammatory drug (NSAID). In the United States, ketorolac, ibuprofen, and acetaminophen all have been approved for short-term parenteral use. In opioid-naïve patients, a standard dose of ketorolac can provide analgesia equivalent to a parenteral dose of morphine of 10 mg (45). The addition of intravenous ketoprofen (not approved in the United States) to intravenous PCA with tramadol after major gynecologic cancer surgery was shown to significantly reduce opioid consumption (46). At the present time in the United States, patients who are highly predisposed to opioid side effects or toxicity, such as those with severe preexisting lung disease, may benefit from a trial of one of the intravenous nonopioid analgesics, either in lieu of opioid therapy or in combination with an opioid. Ketorolac and ibuprofen should not be used when NSAID treatment is contraindicated.

Patient-Controlled Analgesia

PCA has achieved great popularity in the management of postoperative pain and there is strong evidence that it improves analgesia, decreases the risk of pulmonary complications, and increases patient satisfaction when compared to conventional opioid analgesia (47). Theoretically, the self-administration of small doses on a frequent basis allows the patient to tailor the dose to the pain and enhance a sense of personal control while achieving a more stable plasma drug concentration. However, not all studies of this modality have been positive. For example, a randomized, controlled trial of 227 gynecologic cancer patients undergoing intra-abdominal surgery found that patients who were switched from parenteral to oral morphine on the first postoperative day experienced the same degree of pain control as those who received parenteral morphine via PCA pump (48). The latter studies suggest that careful attention to dosing rather than the availability of a pump per se is the key factor in achieving adequate pain control.

Other Approaches to Acute Pain Management

Numerous alternative approaches to postoperative pain management have been explored. Some require the expertise of pain specialists.

Preemptive Analgesia

The administration of an analgesic prior to surgical tissue injury may reduce postoperative pain and opioid requirements, and possibly have longer-term benefits (49). There are conflicting data, however, and the influence of type of analgesia, timing, and range of outcomes has not been elucidated. The role of this strategy in gynecologic surgery is unclear and it is not generally pursued.

Oral Pretreatment and Postoperative Combination Therapy

Pretreatment with sustained-release morphine or oxycodone reduces postoperative pain and analgesia requirements (50,51). This technique is seldom used, but may be an option in patients whose postoperative pain management is expected to be problematic.

Presurgical or postsurgical addition of an NSAID in combination with an opioid can augment analgesia and reduce the use of opioids, potentially leading to reduction of opioid side effects. A recent controlled trial, for example, demonstrated that postoperative celecoxib improved outcomes and was well tolerated in patients undergoing laparoscopic surgery (52). Equally

important, there is now substantial data demonstrating that the combination of an opioid and gabapentin, a neuronal calcium channel modulator widely used for the treatment of chronic neuropathic pain, improves a range of outcomes in diverse surgeries, including hysterectomy (53).

Intraspinal Analgesia

Epidural analgesia is now common practice in many hospitals. There is strong evidence that analgesia is better with this approach than with parenteral opioids (54–57). There may also be a lower risk of some postoperative complications (58,59). Some studies suggest benefits that are prolonged into the recovery phase after surgery, but the extant data are insufficient to judge these benefits adequately (55). Some side effects are more likely to occur with this technique than with conventional systemic opioid therapy, including pruritus and hypotension; resources, including staff with special competencies, are needed to implement the approach safely.

Given the abundant evidence of better analgesia and related outcomes, patients undergoing major gynecologic surgery should be considered for epidural analgesia if the resources exist to provide it. Although there is less clinical experience in the use of subarachnoid opioid administration for postoperative pain, the technique can also provide excellent relief (60–62).

Regional Anesthetic Techniques

There are numerous regional anesthetic techniques that may be useful for the management of acute pain. The simplest is the application of local anesthetic at the surgical site. Topical anesthetics that are longer acting are in development and may offer substantial benefits in the future.

Neural blockade capable of denervating the painful site is a potential approach in most cases. Catheters that deliver local anesthetic at a dose high enough to produce a sensory block can be placed in the epidural space or along peripheral nerves or plexus. Regional anesthesia can be used during an operation and then continued into the postoperative setting for pain control. For example, a recent study demonstrated that subarachnoid block for vaginal hysterectomy yielded significantly better immediate postoperative analgesia versus standard general anesthesia (63).

Other Approaches

Transcutaneous electrical nerve stimulation (TENS) has been suggested to be a useful modality for incisional pain after abdominal surgery (64). Despite the evident simplicity and safety of the approach, there has been little application of its potential.

Cognitive approaches, including stress reduction, relaxation, hypnosis, and distraction techniques, have also reduced postoperative pain and analgesic requirements (65,66). These techniques are labor intensive and are almost never sufficient as the sole means of analgesia. Nonetheless, studies have established that higher levels of anxiety and depression can negatively influence postoperative pain and analgesic requirements (67), and efforts to reduce anxiety through preoperative education and postoperative psychological interventions are likely to have salutary effects.

MANAGEMENT OF CHRONIC CANCER PAIN

The successful management of acute postoperative pain is an important concern of the gynecologic oncologist, and optimal

pain management should be considered a standard of care. The treatment of chronic pain is a far more challenging problem, particularly among those with advanced illness.

Cancer Pain, Symptom Distress, and Palliative Care

Most cancer patients who experience chronic pain also develop other physical and psychologic symptoms. Pain, fatigue, and psychologic distress are the most prevalent symptoms across populations (68,69). A broad assessment of symptom distress, followed by concurrent therapy of the most problematic symptoms other than pain, is a fundamental aspect of pain management.

Symptom distress, in turn, is only one aspect of the multifaceted problem of suffering (29,30,70). The assessment of suffering requires an evaluation in multiple domains, including the physical, psychologic, social, and spiritual. This in turn requires open and ongoing communication between the clinician and the patient.

The assessment and management of problems that relate to the broad constructs of suffering and quality of life are part of the therapeutic model of palliative care, which focuses on all patients with serious or life-threatening illness and their families. This therapeutic approach aims to reduce illness burden and enhance the quality of life of the patient and family throughout the course of the disease. In the United States, palliative care is rapidly evolving. Specialist care now has a well-defined purview, as codified in a consensus document published by the National Consensus Project for Quality Palliative Care (71). The American Board of Medical Specialties approved Hospice and Palliative Medicine as a formal subspecialty, and in an unprecedented event, ten separate primary boards are cosponsoring, including the American Board of Obstetrics and Gynecology. Specialist care is now being provided by institution-based palliative care programs, which now exist in almost 70% of U.S. hospitals with 50 beds or more. Specialist care in the setting of advanced illness is provided through more than 5,000 hospice agencies in the United States.

Specialist-level palliative care is provided by interdisciplinary teams, each member of which has special competencies. In addition to the board certification for physicians, nurses, and social workers are able to obtain certificates that confirm special knowledge and skills.

In contrast to specialist-level care, generalist-level palliative care should be considered a best practice for oncologists and others involved in the day-to-day management of patients with a serious illness such as a gynecologic cancer. Physicians must understand the necessity of palliative care, that is, interventions that may reduce illness burden or maintain quality of life, from the time of diagnosis onward. They must acknowledge the multidimensional nature of this endeavor, including a focus on communicating well, setting goals, coordinating care, sharing decision making, promoting advance care planning, managing symptoms, providing psychosocial and spiritual support, addressing practical needs in the home, assisting the family as needed, and dealing with the challenges of end-of-life care when this is necessary. Referral to specialist services to address complex needs, or provide hospice home care services, is central to the role of the generalist.

General Principles of Pain Management

The development of a successful strategy for pain management must consider the etiology and pathophysiology of pain, the patient's medical status, and the goals of care. Although the main approach for the management of cancer pain is opioid-based

pharmacotherapy, other interventions, including disease-oriented treatments (e.g., surgery, chemotherapy, or radiation) or other analgesic techniques, may be appropriate in selected cases.

Role of Primary Therapies

Effective treatment of the pathology underlying the pain can be analgesic (72,73). Primary treatment includes antineoplastic therapies and interventions directed at specific structural pathologies (e.g., lysis of adhesions). There is evidence in a limited number of cancers that specific chemotherapy regimens yield analgesic effects and it is a common observation that patients who attain a partial or complete response also experience improved symptoms. In a study of patients with metastatic breast cancer, for example, palliative chemotherapy with doxorubicin with or without vinorelbine resulted in an improvement of pain in 60.4% of the 111 patients who suffered from pain at baseline (74); although patients with an objective tumor response were more likely to have an improvement in pain (84.9%), fully 61% of patients with stable disease also benefited. In a small study of patients with advanced ovarian cancer, palliative chemotherapy was associated with improvement in symptom control, emotional well-being, and global quality of life (75). In a study of patients with recurrent/advanced cervical cancer, 67% of patients experienced improvement of pain after alternating treatment with PBM (platinum, bleomycin, and methotrexate) and PFU (platinum and 5-fluorouracil [5-FU]) (76).

Radiation therapy commonly is used to manage pain and there is evidence that it can provide effective and durable palliation of pain and other symptoms in chemotherapy-refractory patients with ovarian cancer (77,78) and cervical cancer (79). Radiation therapy can also provide analgesia to as many as 80% of those treated for bone metastases (80). Patients with widespread bone metastasis or bone pain refractory to local field radiotherapy may benefit from treatment with radiopharmaceuticals, such as strontium 89 or samarium-153 (81). In addition, analgesia may be an expected result when radiation is used to treat epidural disease, tumor ulceration, cerebral metastases, superior vena cava obstruction, and bronchial obstruction.

Unfortunately, many patients with chronic cancer pain have no option for primary antineoplastic therapy or did not benefit when it was provided. The approach to these patients involves a diverse group of primary analgesic treatments (Table 31.4). Several concurrent interventions are often required to manage the pain. The benefits of analgesic therapies must be balanced against the side effects they produce in a way that optimizes the outcome for the patient. Repeated assessments, performed as part of a broader approach to palliative care, are essential in this process and often lead to adjustments in the therapy.

THERAPEUTIC APPROACHES: PHARMACOLOGIC MANAGEMENT

Prospective trials indicate that more than 70% of patients can achieve adequate relief of cancer pain using a pharmacologic approach (3,12–14). Effective pain management requires expertise in the administration of 3 groups of analgesic medications: NSAIDs, opioid analgesics, and adjuvant analgesics. The term *adjuvant analgesic* is applied to a diverse group of drugs that have primary indications other than pain but can be effective analgesics in specific circumstances, such as in the treatment of neuropathic pain.

A model approach to the selection of these drugs, known as the “analgesic ladder,” was developed by the World Health Organization (WHO) in the 1980s and remains influential today (Fig. 31.2) (3). According to this approach, patients with mild to

moderate cancer-related pain are first treated with acetaminophen or an NSAID. This drug is combined with an adjuvant drug that can be selected either to provide additional analgesia (i.e., an adjuvant analgesic) or to treat a side effect of the analgesic or a coexisting symptom. Patients who present with moderate to severe pain, or who do not achieve adequate relief after a trial of an NSAID, should be treated with an opioid conventionally used to treat pain of this intensity (previously designated a “weak” opioid), which is typically combined with an NSAID and may be administered with an adjuvant if there is an indication for one. Those who present with severe pain or who do not achieve adequate relief following appropriate administration of

FIGURE 31.2 The 3-step “analgesic ladder” proposed by an expert committee of the Cancer Unit of the World Health Organization. Source: Reproduced with permission from the World Health Organization. *Cancer Pain Relief*. 2nd ed. Geneva, Switzerland: World Health Organization; 1996.

drugs on the second rung of the analgesic ladder should receive an opioid conventionally used for severe pain (previously called a “strong” opioid), which may be combined with an NSAID or an adjuvant drug as indicated.

The analgesic ladder is important historically and is still widely cited in the developing world in an effort to encourage policy makers to expand medical access to opioid drugs. It is a limited clinical guideline in most developed countries, where access to numerous opioid formulations and other analgesic modalities has influenced clinical practice. Nonetheless, the fundamental concept promoted by the analgesic ladder model—opioid therapy on a long-term basis should be considered the mainstay for the therapy of chronic moderate to severe cancer-related pain—remains widely accepted and a very important message of the original paradigm.

Nonsteroidal Anti-Inflammatory Drugs

In the United States, the nonopioid analgesics comprise acetaminophen and the NSAIDs (Table 31.5). These drugs have a well-established role in the treatment of cancer pain (82–85). Based on clinical observations, NSAIDs appear to be especially useful in patients with bone pain or pain related to grossly inflammatory lesions, and relatively less useful in patients with neuropathic pain (86). In addition, NSAIDs have an opioid-sparing effect that may be helpful to prevent the occurrence of dose-related side effects (87,88).

NSAIDs inhibit the enzyme cyclo-oxygenase (COX) to reduce production of peripheral and central prostaglandins, and this action presumably underlies their analgesic effects. There are multiple forms of COX. COX-1 is relatively more constitutive, physiologically active in many tissues, and COX-2 is relatively inducible, produced as part of the inflammatory cascade.

Compounds that are more selective for COX-2 than COX-1 have a lower risk of inducing gastrointestinal adverse effects (89,90), and some drugs that are relatively COX-2 selective have been labeled in this way and promoted for their enhanced gastrointestinal safety. In the United States, the only drug of the latter type now on the market is celecoxib. Rofecoxib and valdecoxib were previously available, but were taken off the market due to concerns related to cardiovascular safety.

The clinical decision to offer a NSAID to a patient with cancer usually hinges on the assessment of drug-related risk. Gastrointestinal toxicity is well recognized, and in recent years, cardiovascular safety has become a prominent concern. Based on numerous studies, it is most reasonable to conclude that all NSAIDs are prothrombotic and pose an increased risk of peripheral vascular disease, myocardial infarction, transient ischemic attacks, and stroke (91,92). Mechanistically, this risk is associated with COX-2 inhibition, whether produced by the nonselective COX-1 and COX-2 inhibitors or by the COX-2 selective drugs. Although the risk varies across drugs, large comparative studies have been retrospective and results have been conflicting. In the United States, all NSAIDs now have a boxed warning in the package insert, which offer cautions about both gastrointestinal and cardiovascular risk. Among all commercially available NSAIDs, naproxen generally is viewed as having the lowest risk of cardiovascular toxicity.

Although all NSAIDs have the potential to produce adverse gastrointestinal effects, ranging from pain or nausea to frank ulceration and hemorrhage, there are important drug-selective differences. The COX-2 selective agents, such as celecoxib, are less likely to cause these effects, as are several of the so-called nonselective agents, such as ibuprofen and diclofenac. Coadministration of a proton pump inhibitor, such as omeprazole or misoprostol, also should be considered to reduce the risk of gastrointestinal damage induced by NSAIDs (93).

Table 31.5 Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

Class and Generic Name	Trade Name	Approx. Half-Life (h)	Dosing Schedule	Recommended Starting Dose ^a	Comment ^b
<i>P-Aminophenol Derivatives</i>					
Acetaminophen ^c	Tylenol, Datriol, Panadol	3–4	q 4–6 h	650 mg q 4 h (5 doses daily)	Overdosage produces hepatic toxicity. Not anti-inflammatory and therefore not preferred as first-line analgesic or coanalgesic in patients with bone pain. Lack of GI or platelet toxicity; however, may be important in some cancer patients. At high doses, liver function tests should be monitored.
<i>Napthylalkanones</i>					
Nabumetone	Relafen	22–30	q 24 h	500–1,000 mg q 12 h	Appears to have a relatively low risk of GI toxicity; once-daily dosing can be useful.
<i>Salicylates</i>					
Acetylsalicylic acid ^c	Aspirin	3–12 ^d	q 4–6 h	650 mg q 4 h (5 doses daily)	Standard for comparison. May not be tolerated as well as some of the newer NSAIDs.
Diflunisal ^c	Dolobid, Dolobis	8–12	q 12 h	1,000 mg × 1, then 500 mg q 12 h	Less GI toxicity than aspirin
Choline magnesium trisalicylate ^c	Trilisate	8–12	q 12 h	500–1,000 mg q 12 h	Choline magnesium trisalicylate and salsalate have minimal GI toxicity and no effect on platelet aggregation despite anti-inflammatory effects. May therefore be particularly useful in some cancer patients.
Salsalate	Disalacid	8–12	q 12 h	500–1,000 mg q 12 h	

(continued)

Table 31.5 Nonsteroidal Anti-Inflammatory Drugs (NSAIDs) (Continued)*Propionic Acids*

Ibuprofen ^c	Motrin, Advil, Nuprin	3–4	q 4–8 h	400–600 mg q 8 h	Available over-the-counter.
Naproxen ^c	Naprosyn	13	q 12 h	250–500 mg q 12 h	Available as a suspension.
Naproxen sodium ^c	Aleve, Anaprox, Naprelan	13	q 12 h	275–550 mg q 12 h	—
Fenoprofen	Nalfon, Fenopron, Progesic	2–3	q 6 h	200 mg q 6 h	—
Ketoprofen	Orudis, Oruvail	2–3	q 6–8 h	25–50 mg q 8 h	—
Flurbiprofen ^c	Ansaid	5–6	q 8–12 h	100 mg q 12 h	—
Oxaprozin	Daypro	40	q 24 h	600 mg q 24 h	Once-daily dosing may be useful.

Acetic Acids

Indomethacin	Indocin, Indocid	4–5	q 8–12 h	25 mg q 8 h	Available in sustained-release and rectal formulations. Higher incidence of side effects, particularly GI and CNS, than propionic acids.
Tolmetin	Tolectin	1	q 6–8 h	200 mg q 8 h	
Sulindac	Clinoril	14	q 12 h	150 mg q 12 h	Less renal toxicity than other NSAIDs.
Diclofenac	Voltaren	2	q 6–8 h	25 mg q 8 h	
Ketorolac ^c	Toradol	4–7	q 4–6 h	30–60 mg load, then 15–30 mg q 6 h (parenteral); 10 mg q 6 h (oral)	Only parenteral formulation available. Approved for postoperative use. Experience too limited to evaluate higher doses.

Oxicams

Piroxicam	Feldene	45	q 24 h	20 mg q 24 h	Administration of 40 mg for over 3 wk is associated with a high incidence of peptic ulcer, particularly in the elderly.
-----------	---------	----	--------	--------------	---

Fenamates

Mefenamic acid ^c	Ponstel, Ponstan	2	q 6 h	250 mg q 6 h	Not recommended for use longer than 1 wk and, therefore, not indicated in cancer pain therapy.
-----------------------------	------------------	---	-------	--------------	--

Pyrazoles

Phenylbutazone	Antadol, Butazolidin	50–100	q 6–8 h	100 mg q 8 h	Not a first-line drug owing to risk of serious bone marrow toxicity. Not preferred for cancer pain therapy.
----------------	----------------------	--------	---------	--------------	---

Cox-2 Inhibitors

Celecoxib	Celebrex	11	q 12 h	100–200 mg q 12 h	Fewer GI side effects; no effect on platelet function.
-----------	----------	----	--------	-------------------	--

CNS, central nervous system; GI, gastrointestinal; h, hours.

^aStarting dose should be one-half to two-thirds of the recommended dose for the elderly, those on multiple drugs, and those with renal insufficiency. Doses must be individualized. Low initial doses should be titrated upward if tolerated and clinical effect is inadequate. Doses can be incremented weekly. Studies of NSAIDs in the cancer population are meager; dosing guidelines are thus empiric.

^bWith all NSAIDs, stool guaiac and liver function tests, BUN, creatinine, and urinalysis should be monitored; frequency of monitoring should be increased for those on relatively high doses.

^cPain is approved indication.

^dHalf-life of aspirin increases with dose.

Given their risk profile, NSAIDs should be administered with caution to patients with significant predisposing factors for peptic ulcer disease, cardiovascular disease, renal disease, or bleeding diathesis. If there is no strong contraindication for therapy, patients who are predisposed to ulcer disease should be considered for a trial of celecoxib in the United States and patients who may be at relatively high risk of cardiovascular toxicity should be offered naproxen first. In the setting of renal insufficiency, the safest nonopioid to use is acetaminophen, notwithstanding some data that suggest that this drug can also produce renal toxicity (94).

Other factors may also be important in the selection of an NSAID. First, there is substantial variability in the response of individual patients to different agents, and the response to an NSAID in the past should guide drug selection in the present. Second, it may be useful to consider the drug's duration of effect when selecting an NSAID. The need to improve treatment adherence or provide a simpler dosing regimen encourages the use of a drug that can be administered once daily (e.g., nabumetone) or twice daily (e.g., celecoxib and many others), whereas the desire for as-needed dosing suggests the use of a short-duration drug (e.g., ibuprofen). Finally, drug selection may be influenced by cost, which varies greatly among both drugs and pharmacies.

The toxicities associated with the use of NSAIDs are dose-related and often occult until severe morbidity occurs. Although patients with cancer pain are commonly treated with standard doses, it is reasonable to explore the dose range and seek the minimal effective dose for long-term therapy. Dose escalation in poor responders is limited by dose-related toxicities and a ceiling dose for analgesia above which additional dose increments fail to produce more relief (95). If an increase in dose maintains the therapy in the conventionally accepted safe range and provides more analgesia, it should be continued. The lack of additional pain relief following a dose increase, however, suggests that the ceiling has been reached, and the dose can then be lowered to the previously effective dose or the drug can be discontinued. All patients receiving an NSAID should be evaluated periodically for occult fecal blood, changes in blood pressure, and effects on renal or hepatic function.

Opioid Analgesics

Expertise in the administration of opioid analgesics (Table 31.6) is the foundation of cancer pain management. The clinician should have knowledge of opioid pharmacology and a clear grasp of practical guidelines for dosing (96,97).

Opioid Classes

Based on receptor interactions, the opioid analgesics can be divided broadly into pure agonists and agonist-antagonists. The pure agonist drugs used in the management of chronic cancer pain are agonists at the μ -receptor subtype. The agonist-antagonist drugs comprise a mixed agonist-antagonist subclass, which includes drugs that are weak antagonists at the μ receptor and agonists at another receptor subtype, and a partial agonist subclass, which includes drugs that are partial agonists at the μ receptor. In the United States, the mixed agonist-antagonist drugs include pentazocine, nalbuphine, dezocine, and butorphanol, and the partial agonists include buprenorphine.

All the agonist-antagonist drugs share properties that together suggest a limited role in the management of chronic cancer pain. These drugs have a ceiling dose for analgesia, and all have the potential to produce an abstinence syndrome in patients already physically dependent on an agonist drug. Some

of the mixed agonist-antagonists, particularly pentazocine, are also more likely to produce psychotomimetic effects than the pure agonist drugs. In patients with chronic pain, the lack of oral formulations for all but pentazocine and buprenorphine (sublingual formulation) also limits the utility of these drugs. A transdermal buprenorphine patch recently became available in the United States; although this formulation increases the utility of buprenorphine for chronic pain, it has been designed for patients who are opioid-naïve or have very limited opioid exposure, and both this characteristic and its cost presumably will limit its use for cancer pain.

Agonist drugs, the prototype of which is morphine, are preferred in the management of chronic cancer pain (Table 31.6). To optimize the administration of these drugs, widely accepted dosing guidelines must be applied systematically.

“Weak” versus “Strong” Opioids. Unlike the division of the opioids into agonist and agonist-antagonist classes, the distinction between “weak” opioids and “strong” opioids, which was originally incorporated into the WHO analgesic ladder approach (3), is more operational than pharmacologic. The so-called weak opioids are now designated as those that are conventionally administered orally for moderate pain in patients with no or limited prior opioid exposure (second rung of the analgesic ladder), and the so-called strong opioids are those that are conventionally used to treat severe pain or moderate to severe pain in patients already using an opioid (third rung of the analgesic ladder). In the United States, the former group comprises codeine, hydrocodone, dihydrocodeine, oxycodone, and occasionally meperidine. Tramadol, a unique centrally acting analgesic with a mechanism of action that is partly opioid, also is generally included with this group, and tapentadol, a newer analgesic with a mixed mechanism similar to tramadol, may also be included. The other opioids used conventionally on the third rung of the analgesic ladder include morphine, hydromorphone, oxycodone, oxymorphone, levorphanol, fentanyl, and methadone.

The designation of the drugs conventionally used to treat moderate pain as “weak” was a misnomer because none of these drugs is characterized by a ceiling effect that would limit its use. Rather, other considerations have led to the customary use of these opioids at doses limited to those capable of treating moderate pain in the relatively nontolerant patient. For example, the dose of any opioid combined in a single tablet with acetaminophen or aspirin can only be escalated until the dose of the nonopioid coanalgesic reaches a level associated with toxicity. Hydrocodone and dihydrocodeine are available only in such combinations, and most of the other drugs in this group may be administered in this form.

Meperidine should not be used at higher doses because of the risk of enhanced toxicity due to accumulation of a metabolite. A similar concern colored the use of propoxyphene, which is no longer available in the United States. The metabolite of meperidine, normeperidine, has been observed to produce clinically relevant side effects in the cancer population, including tremulousness, hyperreflexia, myoclonus, and even seizures (98). This risk suggests that meperidine should not be used in the management of cancer pain.

As suggested by the analgesic ladder, the simplest approach to the management of moderate pain in the cancer patient with limited or no prior exposure to opioids begins with a combination product containing a nonopioid drug and an opioid, usually codeine, oxycodone, or hydrocodone. The dose can be increased to maximally safe levels of the coanalgesic; in products containing acetaminophen, this is usually 4 g per day. A lower maximal total daily dose—2.6 g—should be applied in the elderly, patients with any type of hepatic dysfunction, and those who may be unable to comply with the instruction to avoid all over-the-counter medications containing this drug.

Table 31.6 Opioid Analgesics

Drug	Dose (mg) Equianalgesic to Morphine 10 mg IM ^a PO	IM	Half-Life (h)	Peak Effect (h)	Duration (h)	Comment ^b
Morphine	20–30 ^c	10	2–3	0.5–1.0	3–6	Standard for comparison
Morphine CR	20–30	10	2–3	3–4	8–12	Various formulations are not bioequivalent
Morphine SR	20–30	10	2–3	2–3	12–24	—
Codeine	200	130	2–3	1.5–2.0	3–6	Combined with aspirin or acetaminophen. Usually for moderate pain. Also available without coanalgesic
Hydromorphone	7.5	1.5	2–3	0.5–1.0	2–4	Potency may be greater, i.e., hydromorphone: morphine = 3:1 rather than 6.7:1 during prolonged use
Oxycodone	20	—	2–3	1	3–4	Combined with aspirin or acetaminophen, for moderate pain; available orally without coanalgesic and useful for severe pain
Oxycodone CR	20	—	2–3	2–3	8–12	—
Oxymorphone	10 (rectal)	1	2–3	1.5–3.0	2–4	—
Oxymorphone CR	20 (oral)	—	2–3	1.5–3.0	2–4	—
Methadone	20	10	12–190	0.5–1.5	4–12	Although 1:1 ratio with morphine was in single-dose study, there is a change with chronic dosing and large dose reduction (75%–90%) is needed when switching to methadone. Risk of delayed toxicity
Levorphanol	4	2	12–15	0.5–1	4–6	Usage limited because only 2 mg tablets are available
Fentanyl	—	—	7–12	—	—	Can be administered as a continuous IV infusion or SC infusion; based on clinical experience, 100 µg/h is roughly equianalgesic to morphine 4 mg/h
Fentanyl TTS	—	—	16–24	—	48–72	Based on clinical experience, 100 µg is roughly equianalgesic to morphine 4 mg
Meperidine	300	75	2–3	0.5–1.0	3–4	Not preferred for cancer patients owing to potential toxicity
Tapentadol	—	—	4–5	1	4–6	—

IM, intramuscular; IV, intravenous; SC, subcutaneous.

^aDose that provides analgesia equivalent to 10 mg intramuscular morphine.

^bAll opioids may produce various common side effects (e.g., constipation, nausea, sedation). Respiratory depression is rare in cancer patients.

^cExtensive survey data suggest that the relative potency of IM:PO morphine of 1:16 changes to 1:23 with chronic dosing.

Selection of an Opioid

The selection of an opioid for severe cancer pain is empirical. Traditionally, morphine was considered to be the preferred first-line drug based on worldwide experience, ease of dosing, and the availability of numerous formulations. The intraindividual variability in the response to the different opioids is very substantial, however, and any of the other drugs may yield a better response in the individual patient. This variability also suggests that therapeutic failure with one drug may be followed by remarkable success with another (99).

The predominant metabolic pathway for morphine is glucuronidation to morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G), and the accumulation of morphine metabolites may be associated with side effects, such as myoclonus and chronic nausea (100). Renal insufficiency results in accumulation of M3G and M6G (101,102). For this reason, morphine should be administered cautiously to patients with renal insufficiency. The occurrence of morphine toxicity in these patients should be followed by a trial of an alternative opioid, such as hydromorphone or fentanyl. Although the supporting

data are limited, morphine is often viewed unfavorably when patients have very poor renal function or are on dialysis or have renal function that is expected to change. In the latter situations, studies are inadequate to generate guidelines that are evidence based, but hydromorphone and fentanyl are often preferred (103). Given concern about the theoretical accumulation of hydromorphone metabolites, some authors recommend against this drug as well (104).

The selection of an opioid for the treatment of severe cancer pain is also influenced by pharmacokinetic factors, the most salient of which is duration of effect. In an effort to improve adherence and convenience, numerous long-acting modified-release formulations of short half-life opioids have been developed. Oral once-daily or twice-daily formulations of morphine, oxycodone, oxymorphone, and hydromorphone are available in the United States and other countries. Transdermal fentanyl provides a dosing interval of 2 to 3 days and is preferred by some patients.

Although both levorphanol and methadone have relatively long half-lives (Table 31.6), patients typically require doses at least every 6 hours to maintain stable effects. Methadone has

become an increasingly popular drug for chronic pain, presumably because of its low cost, potential for unexpectedly high potency, and relatively low abuse potential and low likelihood of diversion by individuals with a history of substance use disorder. Clinical experience suggests that rotation to methadone after inadequate treatment with another opioid can indeed produce surprisingly good results, an outcome that has been speculated to be related to the d-isomer in the formulation that is commercially available in most countries; this isomer is not an opioid, but rather blocks another receptor (the N-methyl-d-aspartate, NMDA, receptor) which may potentiate analgesia or reverse some degree of opioid tolerance (105,106).

Methadone is a challenging drug to use, however, and clinicians must understand its unique pharmacology to administer it in a safe manner. Methadone's half-life ranges between 12 and 190 hours, and substantial delayed toxicity has been observed many days after methadone treatment was begun or altered (107). Its potential to have an unexpectedly high potency when substituting for another opioid increases the challenge of dose selection when starting the drug. It can prolong the QTc interval (108,109) a risk that suggests the need to obtain a baseline ECG in patients who may be predisposed to this phenomenon and periodic ECG monitoring thereafter (110). Given the increased potential for serious toxicity and the need for prolonged monitoring with methadone, its administration should be undertaken only by clinicians with the knowledge and experience necessary to ensure safety.

The patient's previous favorable experience with opioid drugs should also be considered when choosing an opioid. The exception to this is meperidine, the toxic metabolite of which may accumulate with repeated dosing. A favorable experience with this drug during short-term administration should not be viewed as predictive of the response to chronic dosing.

Routes of Administration

The oral and transdermal routes are preferred in the management of chronic cancer pain. Alternative routes may be required, however, and the clinician must recognize their indications and be familiar with the accepted approaches. In a survey of patients with advanced cancer, more than half required 2 or more routes of administration prior to death and almost a quarter required three or more (111).

Transdermal Delivery. The transdermal route of administration is available for the highly lipophilic opioids buprenorphine and fentanyl (112). Transdermal fentanyl, which offers a 48- to 72-hour dosing interval, is preferred by some patients and may be associated with relatively less constipation (113). The transdermal route may be very useful for the patient who is unable to swallow or absorb an orally administered opioid. This is particularly appropriate when the underlying pain syndrome is relatively stable; pains that are rapidly fluctuating and require multiple supplemental doses may be more easily managed using an ambulatory infusion device with a PCA option. Transdermal fentanyl is relatively contraindicated in patients with anticipated episodes of fever; increased ambient temperature changes the delivery characteristics of the patch and fever may be associated with overdose.

Although buprenorphine is a partial agonist and has a ceiling dose, and a capacity to induce abstinence if administered to a patient who is already physically dependent on another opioid, a recent observational study suggests that some patients with severe cancer can benefit and make use of this formulation until death (114). The transdermal formulation of this drug available in the U.S., provides a relatively low dose range, however, and suggests overall a limited utility in cancer pain.

Rectal. Rectal formulations of oxymorphone, hydromorphone, and morphine are available in the United States. There

also is anecdotal experience with rectal administration of controlled-release morphine or oxycodone tablets. The rectal route usually is considered for patients who are relatively opioid non-tolerant and become temporarily unable to take oral medications. The potency of opioids administered rectally is believed to approximate oral dosing (115). Absorption is variable, and relative potency may be higher or lower than expected depending on a variety of factors, including location of the suppository (low in the rectum, where the blood supply is systemic, or high in the rectum, where blood flows through the portal circulation) and contents of the rectum at the time of dosing.

Transmucosal. Absorption through the oral or nasal cavity potentially can occur with any opioid, and those that are lipophilic and relatively potent may be absorbed sufficiently to have clinical use (116). Multiple types of transmucosal formulations of fentanyl have been approved after having been shown to be safe and efficacious when used as a "rescue" dose for the treatment of breakthrough pain in cancer patients receiving a fixed-schedule opioid (117,118). These formulations include an intraoral lozenge, a buccal tablet, a buccal patch, a sublingual tablet, and a nasal spray. All are efficacious and have an onset of action faster than orally administered drugs. There are very few comparative trials and the appropriate positioning of these drugs against relatively less costly ones in the therapeutic armamentarium for cancer-related breakthrough pain remains uncertain. Patients who demonstrate that a short-acting oral opioid does not satisfactorily address a breakthrough pain due to a slow onset of effect, those with very rapid onset breakthrough pains, and those who have a particularly good response to fentanyl may be considered empirically for a trial of one of these drugs. There are insufficient data to recommend one formulation over another and this decision usually will be based on availability, cost, and patient preference. Given the perception that rapid-onset formulations address an unmet clinical need, other formulations are in development.

In some clinical situations, a trial of an injectable formulation placed under the tongue is reasonable. Although there is considerable experience in the use of sublingual administration of concentrated oral morphine solution during the care of patients at the end of life, this drug is relatively hydrophilic, and is poorly absorbed by this route; it is likely that most of the effects obtained occur following enteral absorption after swallowing.

Intranasal butorphanol is available, but as noted, this opioid is an agonist-antagonist and has characteristics that make it unfavorable for long-term administration to cancer patients. It is rarely used in this setting. Sublingual preparations of buprenorphine indicated in the United States for the office-based treatment of addiction have little evidence of safety and efficacy for cancer pain.

Parenteral Injection. Patients who are unable to swallow or absorb opioid drugs are candidates for long-term parenteral dosing. Repetitive intramuscular or subcutaneous injections are painful and should be rarely considered. Repetitive intravenous injections may be effective, but they usually require skilled nursing and may be associated with prominent "bolus" effects (toxicity at peak concentration, pain breakthrough at the trough, or both). Repetitive dosing through a "butterfly" needle placed under the skin has been used effectively in end-of-life care and experience suggests that the needle can be in place for a week without the development of local pain or other problems.

Continuous Infusion. Continuous infusion eliminates the fluctuations in plasma concentration associated with repetitive bolus injections. Any opioid available in an injectable formulation can be used for continuous infusion. The availability of continuous subcutaneous infusion using ambulatory infusion devices has markedly enhanced the clinical utility of infusion techniques, allowing long-term administration of opioids and other drugs in the home environment (119). A diverse group

of pumps that range considerably in features, complexity, and cost are now available, and the clinician often has the option of selecting a pump based on the needs and resources of the patient. PCA can be combined with continuous infusion to address episodic pains. In most cities, skilled nursing organizations can assist in the management of therapy at home.

Intraspinal Opioids. The discovery of opioid receptors in the spinal cord provided the foundation for the development of techniques to deliver opioid analgesics intraspinally. Intraspinal administration can provide selective analgesia (i.e., without the sensory or motor blockade produced by local anesthetics) at doses lower than those required systemically. The strongest indication for a trial of intraspinal opioid administration is the occurrence of intolerable somnolence or confusion in patients who are not experiencing adequate analgesia during systemic opioid treatment of pain.

Many methods of intraspinal opioid administration are now in use (120). The most commonly used include a percutaneous epidural catheter, which is usually tunneled to the anterior abdominal wall and there connected to an ambulatory infusion pump; a totally implanted epidural catheter connected to a subcutaneous portal, which in turn is connected to an ambulatory pump; and an intrathecal catheter connected to a totally implanted continuous infusion device. The preferred drugs for chronic intraspinal infusion are morphine and hydromorphone, but many others are used empirically, and admixtures (e.g., opioid plus local anesthetic or clonidine, or both) are now commonplace.

The use of intraspinal infusion in the management of cancer pain is likely to increase with further evidence of favorable outcomes in the oncology population (121). Implantable pump systems, which are refilled percutaneously, are often chosen for patients with life expectancies of 3 or more months. A controlled trial that compared neuraxial infusion to comprehensive medical management demonstrated that the spinal opioid treatment improved pain, side effects, quality of life, and even survival (122). The potential utility of neuraxial analgesia is also likely to change with the advent of more choices in drug selection.

Based on a systematic review of the literature (123), an expert panel created an algorithm for the progressive use of an array of drugs during intrathecal therapy (124). Therapy is initiated with a single-agent opioid (either morphine or hydromorphone). If adequate pain relief cannot be achieved, a second agent is added, either bupivacaine or clonidine. Clonidine, an α_2 -adrenergic agonist that was shown in a controlled trial to be effective in neuraxial analgesia (125), is one of several classes of nonopioid and nonanesthetic drugs now being used. Ziconotide, a unique calcium-channel blocker, is now available in the United States and has been shown to be effective for cancer pain in controlled trials (126). A 2007 update of the evidence-based algorithm for drug selection during neuraxial infusion incorporates these and other agents (127). Intraspinal therapy is now often initiated with a combination of drugs in an effort to reduce side effects, such as sensory and motor block, urinary retention, pruritus, and nausea, and potentiate analgesia (128).

Guidelines for the Administration of Opioid Drugs

As noted, all patients who develop moderate to severe persistent pain should be considered for an opioid-based regimen. The opioid-naïve patient usually is offered a short-acting combination product (conventionally used on the analgesic ladder's second rung). It is acceptable, however, to initiate therapy with a long-acting formulation, as long as the dose is appropriate (129). For example, long-acting morphine can be started at a dose of 15 mg twice daily, or 20 to 30 mg once daily, depending on the formulation. Long-acting oxycodone or oxymorphone

can be started at doses of 10 mg twice daily or 5 mg twice daily, respectively. Transdermal fentanyl can be initiated at 12 $\mu\text{g}/\text{h}$ in opioid-naïve patients. Given the availability of these long-acting formulations in doses appropriate for the opioid-naïve, the decision to start a short-acting or long-acting drug in a patient with new-onset persistent pain is a clinical judgment based on patient preference, convenience, cost and availability, and experience.

If a patient is receiving a short-acting drug, but pain is not controlled, it is conventional practice to switch to a single-entity pure μ agonist (third-rung drug), typically in a long-acting formulation. Starting doses may be slightly higher if the patient has been requiring regular administration of the short-acting drug. On a daily basis, the milligram dose of a long-acting drug is the same as the short-acting formulation of the same drug.

Following selection of a starting dose, dose adjustment is almost always required. Once a favorable balance between analgesia and side effects is obtained, this is usually maintained for a prolonged time unless there is progression in the pain-producing pathology. Although several large surveys have established that patients with stable disease usually demonstrate stable dosing patterns, most patients with cancer pain do not have stable disease. Recurrent pain or the new occurrence of side effects necessitates another period of dose titration. Inadequate adjustment of the dose is probably the most common reason for unsuccessful long-term management of cancer pain.

In all cases, the dose of an opioid should be increased until acceptable analgesia is produced or intolerable and unmanageable side effects supervene. Ceiling doses for the pure agonist opioids have not been identified clinically, and occasionally doses can become extremely high—equivalent to grams of morphine per day—as upward dose titration proceeds. The absolute dose of the opioid is immaterial as long as the balance between analgesia and side effects remains acceptable for the patient.

Surveys have demonstrated that one-half to two-thirds of patients with cancer pain will experience clinically significant breakthrough pain (130,131), and it is common to coadminister a short-acting drug—an approach known as “rescue” dosing—to treat it. As described previously, rapid-onset transmucosal formulations have been developed specifically in an effort to improve the management of breakthrough pain, most of which have a time course that is more rapid than the typical time-action profile of an orally administered opioid.

Treatment of common side effects is an essential element in the successful management of opioid therapy (see below). Patients who experience intolerable toxicity despite treatment should be designated as poorly responsive to the specific drug and route, and an alternative strategy for pain control should be implemented (132–134). This may include more sophisticated management of the treatment-limiting side effect, the addition of a pharmacologic or nonpharmacologic analgesic approach that could reduce the opioid requirement, or opioid rotation.

Opioid rotation, or the switching from one drug to another in an effort to improve the outcomes of an opioid regimen, is now widely used, despite guidelines based on experience rather than research (135). Switching requires an appreciation of relative potency, as codified on the equianalgesic dose table (Table 31.6). To switch to another opioid drug or route, the equianalgesic dose table is used to calculate a dose of the new drug that would be theoretically equianalgesic with the old drug or route. With few exceptions, the dosing regimen based on this calculated dose should be reduced by 25% to 50% to account for incomplete cross-tolerance between drugs; a larger reduction, 75% to 90%, is prudent if the new drug is methadone (because of a unique pharmacology in this agent). In contrast, no reduction in the equianalgesic dose is needed if the switch is to transdermal fentanyl (because a reduction is already built into the recommended equianalgesic ratios).

Management of Common Opioid Side Effects

Although there is no maximum dose or ceiling dose for the μ -agonist opioids, the appearance of side effects imposes a practical limit on dose escalation. Given the importance of side effects in determining the response to an opioid, the successful management of common adverse side effects is a fundamental aspect of therapy (Table 31.7) (136).

Constipation is a highly prevalent side effect of opioid therapy. It may contribute to abdominal pain, distension, nausea, and worsening anorexia, and occasionally may progress to obstipation and bowel obstruction. The management of drug-induced constipation should begin with the elimination of non-essential constipatory drugs and, if possible, an increase in both fluid and fiber intake. Fiber should not be increased in those with likely partial bowel obstruction or marked debility because of the potential for worsening obstruction.

Laxative therapy should be considered whenever constipation cannot be controlled through nutritional measures or chronic opioid treatment is undertaken in a patient predisposed to constipation. If there is reason to believe that obstruction or impaction is present, these problems should be addressed before routine laxative therapy is initiated.

There are numerous types of laxatives, including bulk-forming agents, osmotic agents, lubricants, surfactants, contact cathartics, prokinetic drugs, and opioid antagonists (136,137). The conventional first-line approach is a combination of a stool softener, usually docusate, and a cathartic agent, such as senna. Most patients respond to this therapy. The oral lavage agent, propylene glycol, in a powdered formulation offers another well tolerated and usually effective approach. Other osmotic agents, such as lactulose, are often tried in more refractory cases. Lubiprostone, a chloride channel opener, is available in the United States and also may be considered. A variety of other strategies are used seldom, for challenging cases. These include trials of metoclopramide, misoprostol, colchicine, or donepezil.

Opioid antagonist therapy should be considered when constipation has not responded to routine approaches. A parenteral antagonist, methylnaltrexone, is commercially available in the United States and can be used to manage acute constipation, or with dosing 2 to 3 times weekly, chronic constipation (138–140).

This drug does not cross the blood–brain barrier and reverses opioid-induced constipation through local action on opioid receptors in the gut. It does not cause systemic opioid withdrawal. Another peripherally acting opioid antagonist, alvimopan, is approved for the management of postoperative ileus, and has a similar mode of action. Other compounds of this type are in development.

Opioid antagonist therapy for refractory constipation also can be implemented using oral naloxone. This drug has very limited oral bioavailability and a consequent low risk of withdrawal following oral administration. The starting dose is typically 0.8 mg twice daily; the dose is doubled every 2 to 3 days until favorable effects occur or side effects are experienced (138,140). The daily dose needed to reverse constipation usually is 12 to 18 mg per day.

Nausea or vomiting constitutes a problem for some 10% to 30% of cancer patients receiving opioid therapy (141). Potential contributing etiologies should be evaluated and the treatment adjusted accordingly. If the assessment suggests that factors other than opioids are contributing to the nausea, antiemetic therapy may be combined with specific interventions to reverse or minimize these factors. The usual first-line drugs are the dopamine antagonists, including prochlorperazine, metoclopramide, and haloperidol. Patients with refractory nausea may need other pharmacologic approaches. The antiemetic efficacy of corticosteroids is unexplained; these drugs are clearly

Table 31.7 Commonly Used Pharmacologic Approaches in the Management of Opioid Side Effects

Opioid Side Effect	Treatment
Constipation	Approaches for all patients: - Increase fluid intake and dietary fiber - Ensure coanalgesic or adjuvant (comfort and convenience, etc.) Discuss approaches with patient and select one or more: - Daily contact laxative plus stool softener (e.g., senna plus docusate) - Daily osmotic laxative or lavage agent - Intermittent use of laxative Consider alternative approaches in refractory cases: - Enema - Prokinetic agent (metoclopramide) - Methylnaltrexone or another opioid antagonist
Nausea	Several approaches: - If associated with vertigo or if markedly exacerbated by movement, antiveriginous drug (e.g., scopolamine, meclizine) - If associated with early satiety, prokinetic agent (metoclopramide) - In other cases, dopamine antagonist drugs (e.g., prochlorperazine, chlorpromazine, haloperidol, metoclopramide)
Somnolence, mental clouding	If analgesia is satisfactory, reduce opioid dose by 25% to 50% If analgesia is satisfactory and the toxicity involves confusion, consider a trial of a neuroleptic (e.g., haloperidol) If analgesia is satisfactory and the toxicity is somnolence, consider a trial of a psychostimulant (e.g., methylphenidate) Consider pharmacologic approaches to reduce the opioid requirement (addition of a coanalgesic or adjuvant) Consider trial of an alternative opioid If appropriate, consider nonpharmacologic analgesic approaches

beneficial for some patients. Although a 5HT antagonist, such as ondansetron, can be beneficial for patients with refractory symptoms, they are very costly. Some patients respond to a commercially available cannabinoid, such as tetrahydrocannabinol or nabilone. Others appear to benefit from empirical treatment with a drug used for vertigo, such as meclizine or scopolamine. In difficult cases, combinations of drugs from unrelated classes often are tried.

Sedation or mental clouding is very common when an opioid regimen is begun or the dose increased. Most patients develop

tolerance to this effect relatively quickly, but some do not, and some have other factors that cause cognitive impairment and compound the effect of the opioid. If these side effects are mild, reassurance and education are usually sufficient interventions. When toxicity is severe or persistent enough to compromise the benefits of therapy, other interventions are needed. Treatment of potential etiologies other than the opioid (e.g., elimination of another nonessential drug or treatment of a metabolic disturbance), when feasible and indicated, is the first step in the management of neuropsychologic symptoms. If pain is well controlled, it is reasonable to try an opioid dose reduction of 25% to 50%.

Symptomatic therapies for opioid-induced sedation or mental clouding also should be considered (Table 31.7), but few have been well studied in clinical trials. Methylphenidate has been shown to decrease opioid-induced sedation in cancer patients (142–144). The starting dose is 5 mg at breakfast and at lunchtime. Other psychostimulants that have been used empirically for this indication include dextroamphetamine, amphetamine, modafinil, and armodafinil. A role for modafinil in cancer has been suggested by a positive controlled study that demonstrated improvement across cognitive, mood, and fatigue outcome measures, with the maximum benefit at 8 weeks after initiation of treatment (145). A new stimulant drug, atomoxetine, has a pharmacology that may indicate its utility for fatigue but experience is lacking and it has not yet been widely studied (146).

Tolerance, Physical Dependence, and Addiction

The clinical implications of tolerance, physical dependence, and addiction are commonly misunderstood by patients and clinicians. These misapprehensions may lead to concern about adverse events and, possibly, undertreatment of pain.

Tolerance is a pharmacologic property of opioid drugs defined by the need for escalating doses in order to maintain effects (147,148). Patients may have other reasons for declining analgesic effects, however, among which are progressive nociception and increasing psychologic distress. Abundant survey data suggest that the most common reason for dose increase is worsening pain due to progression of a nociceptive lesion. Most patients with stable disease continue to require the same opioid dose for extremely long periods of time (148,149). Fear of analgesic tolerance should never delay the implementation of opioid therapy, and tolerance should not be invoked to explain the need for higher opioid doses unless a comprehensive reassessment has failed to identify an alternative explanation.

Physical dependence also is a pharmacologic property of opioid drugs, which is defined by the occurrence of an abstinence syndrome following abrupt dose reduction or administration of an antagonist (147). Neither the dose nor the duration of dosing required to produce physical dependence is known, and it is prudent to assume that all patients who have received an opioid drug for more than a few days have the potential for withdrawal. This implies that dosing should not be discontinued suddenly and that antagonist drugs, including the agonist-antagonist opioids, should be avoided.

Patients who become physically dependent on opioids appear to develop increased sensitivity to the effects of antagonist drugs. Very small doses of naloxone may produce a severe abstinence syndrome. For this reason, the use of naloxone should be limited to patients with symptomatic respiratory depression. When naloxone must be used in patients receiving chronic opioid therapy, only a dilute solution (e.g., 0.4 mg in 10 mL saline) should be administered and incremental doses should be given only until respiration improves. The goal of this intervention is improved respiration and not a return of consciousness, which may be associated with recurrent pain and withdrawal phenomena.

Both tolerance and physical dependence are distinct from addiction. Because the labels applied to patients can determine the attitudes and behaviors of caregivers, it is extremely important that appropriate terms are used to describe these phenomena. Patients who are perceived to have the capacity for withdrawal should be labeled physically dependent and not “addicted.”

Addiction is a genetic, psychologic, and behavioral syndrome characterized by craving, loss of control over drug use, compulsive use, and continued use despite harm to the patient or others (147). Although abusable drugs, including opioids, can be shown to have reinforcing effects in animals, the capacity to produce addiction should not be considered an inherent property of the drug. Addiction presumably results from an interaction between the drug and a variety of factors that predispose the individual to compulsive use. These factors probably encompass genetic vulnerability, situational factors, and psychologic disturbances, as well as access to the drug.

Cancer patients who engage in aberrant drug-taking behaviors, such as hoarding or selling, unsanctioned dose escalation, or manipulation of the medical system to obtain additional drugs, may or may not meet criteria for the diagnosis of addiction. If such aberrant behaviors are identified, measures should be taken to eliminate them while a detailed assessment is performed to clarify their meaning. In some cases, aberrant drug-related behaviors appear to be driven by uncontrolled pain. This has been termed pseudoaddiction and is managed by improved efforts to provide pain relief. Occasionally, aberrant behaviors are related to a psychiatric disorder other than addiction or to the development of a mild encephalopathy, which leads to confusion about drug taking. These explanations for problematic drug use are not mutually exclusive and the complexity of the clinical situation requires careful assessment, and often referral of the patient to a pain specialist or an addiction medicine specialist. The clinician must avoid the stigmatizing label of addiction for patients who have reasonable alternative explanations for aberrant behaviors, but be willing to render the diagnosis of addiction in those who actually have this disease.

The risk of true iatrogenic addiction is clearly relevant in judging the overall utility of opioid therapy for chronic cancer pain. There is substantial evidence that this risk is extremely low among those with no prior history of abuse or addiction (150). It is now widely accepted that all patients who are being considered for a trial of an opioid should be evaluated for risk factors that may predict aberrant drug-related behavior, such as a history of substance abuse, a family history of substance abuse, and major psychiatric disorder, but that fear of addiction should not be considered a contraindication to opioid therapy of severe cancer pain. Rather, patients should be stratified by risk before therapy begins, and monitored for aberrant drug-related behavior during the course of therapy. Should concerns arise, the clinician may structure therapy in a way to reduce risk, or refer appropriately.

Adjuvant Drugs

Most patients with cancer pain require multiple drugs for symptom management. Some of these adjuvant drugs are used to treat symptoms other than pain, particularly those that occur as side effects of the opioid (Table 31.7). Other drugs are used in an effort to provide additive analgesia. The latter drugs comprise the NSAIDs and the so-called adjuvant analgesics. Adjuvant analgesics may be defined as drugs that are commercially available for indications other than pain but may be analgesic in selected circumstances (151). In recent years, the number of these drugs has increased substantially, and several have become approved for primary pain indications due to the abundance of evidence for analgesic efficacy.

The adjuvant analgesics are particularly helpful in the treatment of pain syndromes that are often relatively less responsive

to opioids, such as neuropathic pains (Table 31.8). Although neuropathic pains, such as postmastectomy syndrome, painful polyneuropathy, and painful plexopathy, can respond well to an opioid regimen, they are relatively more likely to be poorly responsive and are the most common targets of adjuvant analgesic therapy. In most cases, an adjuvant drug should not be initiated until an opioid has been started and titrated; this approach reduces the risk of additive toxicity (152).

In the setting of advanced illness, corticosteroids are among the adjuvant analgesics commonly used to treat neuropathic pain. These drugs also may improve anorexia, nausea, and fatigue. Among the alternative agents for neuropathic pain are anticonvulsants and antidepressants. Evidence for analgesic efficacy is best for specific anticonvulsants, such as gabapentin and pregabalin (153–157); for the tricyclic antidepressants, such as amitriptyline and desipramine (158,159); and for the serotonin and norepinephrine reuptake inhibitors, specifically duloxetine (160). Gabapentin or pregabalin usually is tried first, given their lack of drug-drug interactions, but sequential trials of various drugs often are required before a well tolerated and effective adjuvant analgesic is identified.

If the drugs with relatively good evidence of analgesic efficacy in neuropathic pain are not tolerated or are ineffective, trials of other anticonvulsants or antidepressants may be undertaken empirically. Other second-line agents for neuropathic pain also are considered in refractory cases. Sodium channel blockers may be given orally (e.g., mexiletine) or tried via brief infusion of lidocaine (161,162). NMDA antagonists have limited evidence of efficacy; ketamine is sometimes tried at subanesthetic doses (163,164). Cannabinoids are analgesic (165–167) and a new cannabis derivative (a 1:1 mixture of tetrahydrocannabinol and cannabidiol) is under development specifically for pain related to advanced cancer. Both the gamma-aminobutyric acid (GABA) agonist, baclofen, and the α_2 -adrenergic drugs, tizanidine and clonidine, are sometimes tried in selected patients with refractory neuropathic pain.

The use of topical agents represents another adjuvant analgesic strategy. A lidocaine patch (Lidoderm®) (168,169) is now available and has been shown to be effective in postherpetic neuralgia. This formulation is commonly tried for all types of neuropathic and musculoskeletal pains. Topical creams also are used empirically in patients with cancer pain, including compounds containing other local anesthetics, capsaicin, an NSAID, a tricyclic antidepressant, or an opioid.

Opioid-refractory malignant bone pain is another syndrome for which adjuvant analgesics often are considered. The preferred drugs include bisphosphonates, radiopharmaceuticals, and calcitonin. Although the bisphosphonates carry the risks of renal insufficiency and osteonecrosis of the jaw, there is evidence that they can improve overall morbidity associated with bone metastases, and a trial of one of these agents is typically considered in the setting of significant bone pain (170).

Adjuvant analgesics also are commonly employed in the setting of bowel obstruction that is not surgically correctable. Aggressive pharmacotherapy, particularly in those with advanced disease, may control symptoms and obviate the need for drainage procedures. Treatment usually involves the combination of anticholinergic drugs (e.g., scopolamine or glycopyrrolate), octreotide, corticosteroids, and opioids (171).

THERAPEUTIC APPROACHES: OTHER APPROACHES IN CHRONIC PAIN MANAGEMENT

Although most patients with cancer pain can achieve adequate relief with pharmacologic approaches alone, a multimodality strategy always should be considered in an effort to optimize

Table 31.8 Adjuvant Analgesics

Indication	Drugs
Neuropathic pain	Antidepressants
	Tricyclic antidepressants
	Amitriptyline
	Desipramine
	“Newer” antidepressants
	Duloxetine
	Anticonvulsants
	Gabapentin
	Pregabalin
	Carbamazepine
	Phenytoin
	Valproate
	Clonazepam
	Lamotrigine
	Sodium channel blockers
	Mexiletine
	Tocainide
	α_2 -adrenergic agonists
	Clonidine
	Tizanidine
	NMDA receptor antagonists
	Ketamine
	Dextromethorphan
	Cannabinoids
	Tetrahydrocannabinol (THC)
	Topical anesthetics
	Capsaicin
	Lidocaine
	Miscellaneous
	Baclofen
	Calcitonin
Bone pain	Bisphosphonates (e.g., pamidronate)
	Calcitonin
	Radiopharmaceuticals (e.g., strontium 89 and samarium 153)
Bowel obstruction	Scopolamine
	Glycopyrrolate
	Octreotide
Multipurpose	Corticosteroids
	Dexamethasone
	Prednisone

the balance between analgesia and side effects, promote better function, or concurrently manage other problems. Multiple therapies commonly are needed to address the broader palliative care concerns of the patient and family, which derive from the complex interaction between pain and suffering (Fig. 31.1).

When the focus is pain control, there are a large number of noninvasive and invasive approaches that may be considered adjunctive to opioid-based pharmacotherapy. Only a small minority of patients will require an invasive analgesic modality if the other therapies are optimally administered.

Interventional Approaches

The interventional strategies include injections, neural blockade, and implant therapies. Trigger point injections may be considered within the purview of all practitioners. Myofascial pains are extremely common in patients with chronic cancer pain, and the use of local anesthetic injections into painful trigger points may be a useful adjunctive approach in these patients (172).

The advances in neuraxial infusion of opioids and other drugs, as described previously, have largely supplanted the neurodestructive approaches that were employed in the past for pain syndromes refractory to systemic opioid therapy. Nonetheless, some types of neural blockade continue to be widely used (120). Sympathetic nerve blocks with local anesthetic are used to manage those cancer-related neuropathic pains that are presumed to be perpetuated at least in part by sympathetic efferent function. Injection of sympathetic nerves innervating viscera also block visceral afferent and the pain relief that results may be largely related to the interruption of the nociceptive input (172).

Temporary somatic nerve blocks may be diagnostic, prognostic, or therapeutic. Diagnostic blocks elucidate the afferent pathways involved in the experience of pain. Prognostic blocks are implemented prior to a neurolytic procedure, and although extensive clinical experience indicates that a favorable response does not predict permanent relief following neurolysis, the failure to achieve pain relief with local anesthetic is commonly viewed as a contraindication to a destructive procedure. Repeated therapeutic blocks with local anesthetic are occasionally used in cancer patients who obtain substantial and fairly prolonged relief after such a temporary block. Recently, local anesthetics have been used to provide more prolonged neural blockade through techniques of perineural or epidural infusion.

Neural blockade with neurolytic solutions, usually alcohol or phenol, have been developed to denervate virtually any area of the body (120). Their use is very limited, however, because of the short-term risks associated with the injection of these substances, such as damage to soft tissues and local hemorrhage or infection, and the longer-term risks of neuritis and deafferentation pain. The one generally accepted exception is celiac plexus blockade for the management of epigastric pain due to neoplastic invasion of the celiac axis. The response to neurolytic celiac plexus blockade in pain due to pancreatic cancer has been observed to be so satisfactory that earlier use is warranted whenever the typical pain syndrome occurs (173).

Intermittent nitrous oxide inhalation is an anesthetic technique that has been proven to be useful in the management of severe breakthrough pain in patients with advanced cancer (174). Although the availability of masks that reduce ambient leakage of the gas has increased the potential usefulness of this approach, it continues to be applied rarely.

Neurostimulatory Approaches

It has been appreciated for some time that stimulation of afferent neural pathways may result in analgesia. The best-known

application of this principle is TENS. Other approaches include counterirritation (i.e., systematic rubbing of the painful part), percutaneous electrical nerve stimulation, dorsal column stimulation, and brain stimulation. Published experience in the use of these modalities for the management of cancer pain is meager. Surveys of the techniques that have been used most extensively in nonmalignant pain (TENS and dorsal column stimulation) suggest that the majority of patients will achieve analgesia soon after the approach is implemented but fewer obtain prolonged relief. A trial of TENS is usually considered in patients with neuropathic pain that has been proven to be difficult to manage with opioids.

Physiatric Approaches

Although evidence from clinical trials is lacking, the potential for analgesic effects from physiatric therapies, including the use of orthoses or prostheses, occupational therapy and physical therapy, and modalities such as heat, cold, vibration, and ultrasound, is well accepted. For example, refractory movement-induced pains may be partially relieved by bracing the painful part, such as in patients with back pain due to metastatic lesions of the spine and those with arm pain related to a malignant brachial plexopathy, and a well-fitting prosthesis can reduce stump pain. In addition to the potential for salutary effects on symptoms, physical therapy and occupational therapy can potentially forestall painful complications, such as contractures, and generally increase well-being.

Neurosurgical Approaches

Procedures designed to denervate the painful area surgically have been developed for every level of the nervous system from peripheral nerves to cortex. Historically, the most useful approach has been cordotomy. Like neurolytic blocks, however, these procedures are rarely considered now, largely due to the advent of more sophisticated, nonneurodestructive interventions such as neuraxial infusion.

Psychologic Approaches

Some patients or families who present with severe psychologic distress may benefit from a multidisciplinary approach in which psychologic interventions are emphasized within a program designed to palliate symptoms and provide family support. These goals may be accomplished in some cases through referral to a hospice or palliative care program. Occasionally, patients with psychiatric disorders are identified, indicating the need for further assessment and treatment by an appropriate specialist (175).

Specific cognitive and behavioral approaches also have been applied in the management of pain and related symptoms (176,177). Cognitive approaches include relaxation training, distraction techniques, hypnosis, and biofeedback, all of which may enhance a patient's sense of personal control and reduce pain. Although many of these approaches require experienced personnel to implement, several forms of relaxation training can be taught by the nonspecialist. Behavioral therapy, which has achieved wide acceptance in the management of nonmalignant pain, is occasionally considered in patients with limited disease whose level of functional impairment is perceived to be out of proportion to the effects of the neoplasm. Cognitive and behavioral psychologic approaches can focus the patient's attention on issues related to function and quality of life and reduce rumination about the disease.

Complementary and Alternative Medicine Approaches

Therapies that are typically considered to be complementary or alternative have had a growing role in pain management (178). These approaches often are very attractive to patients because they endorse a holistic strategy that is perceived as providing hope and self-control. Some interventions that are termed “complementary” are actually used routinely by specialists in pain medicine or palliative care. These include mind-body therapies (e.g., relaxation, meditation, and others), nutritional support, acupuncture, and massage. Other interventions, such as homeopathy, naturopathy, and many others, are considered to be far outside the mainstream and are rarely suggested (179). Health care professionals have the difficult task of expressing concerns about some of the latter therapies, while respecting patients’ pursuit of complementary

treatments that may be beneficial or, at least, offer no significant chance of harm.

CONCLUSION

Pain is highly prevalent among patients with gynecologic tumors. The clinicians involved in the care of these patients have a challenging task in being able to provide state-of-the-art management approaches for both acute pain and chronic pain. Fortunately, the most effective strategy for both acute and chronic pain, namely, opioid-based pharmacotherapy, is clearly within the purview of all practitioners. The knowledge and skills necessary to optimize this therapy, and integrate it with the broader principles of palliative care, are fundamental to the practice of gynecologic oncology.

Nutrition Support of Patients with Gynecologic Cancer

MARK SCHATTNER ■ MOSHE SHIKE

INTRODUCTION

Cachexia and weight loss are common manifestations of cancer and exert major impacts on quality of life and survival. Malnutrition is a complex, multifactorial phenomenon that leads to progressive weight loss and deficiency of specific nutrients. Both cancer and its various therapeutic modalities contribute to cachexia. Advances in understanding nutritional requirements and intermediary metabolism, and major technologic progress in the ability to provide nutritional support, have made it possible to feed almost any patient with cancer. Nevertheless, the indications for and the appropriate use of the various modalities of nutritional support are still evolving, and many questions remain unanswered.

Malnutrition in most patients with cancer is usually a manifestation of general calorie-protein deficits that result in progressive weight loss and weakness; however, it is important to recognize that in some patients, specific nutrient deficiencies, such as magnesium deficiency or vitamin B12 deficiency, can be present even in the absence of weight loss and can contribute significantly to morbidity and even mortality.

Gynecological malignancies and their multimodal therapies may be associated with severe malnutrition. Although some nutritional problems occur in patients with cervical and endometrial cancer, they are most commonly seen in those with ovarian cancer, particularly in advanced stages when intra-abdominal metastasis severely impairs gastrointestinal function. Because of the high incidence of malnutrition and its impact on the patient with cancer, nutritional assessment and appropriate therapy should be integral parts of the overall treatment plan.

NUTRITIONAL ASSESSMENT

Nutritional assessment in cancer patients is an ongoing process. It should be a part of the patient's initial evaluation and should be updated periodically. It is especially important to determine the nutritional state prior to therapeutic interventions as well as during and after an acute illness, with the goal of identifying those patients who could benefit from a specific form of nutritional support. The nutritional assessment method used must be simple, accurate, and inexpensive. Anthropometric parameters, serum protein measurements, and immunologic tests have classically formed the basis of the nutritional evaluation; however, they all have significant deficiencies.

Anthropometric and Biochemical Markers

Anthropometric measurements such as weight, skin fold thickness, mid-arm muscle circumference, and creatinine/height

index can all provide useful information but have major limitations. Change in weight is the single most useful measurement of the nutritional status when the change does not reflect changes in total body water. The often-present edema, effusions, ascites, or intravenous hydration limit the use of weight as a nutritional parameter. In addition, inaccuracies in scales and different clothing in hospitals and at home can often be sources of misleading information on changes in weight. Measurements of skin folds and mid-arm muscle circumference (1) are useful tools in studies but have very limited use in clinical practice. A creatinine/height index derived by dividing the patient's 24-hour creatinine excretion by that of a healthy person of the same height offers a sensitive measure of early protein calorie malnutrition (2) but requires collection of a 24-hour urine specimen and is affected by alterations in renal function, which may not be indicative of the nutritional state.

Low levels of serum proteins such as albumin, prealbumin, transferrin, and retinol-binding protein were classically thought to represent malnutrition. However, in the malnourished sick patient, low levels of these proteins can be nonspecific. They are dependent on intact hepatic synthetic function as well as hydration status. At times, they can be low as a manifestation of severe illness (infection, metastatic cancer, multisystem organ failure) without being a reflection of the nutritional state. In addition, they can function as acute phase reactants and therefore be in the normal or elevated range in a clinically malnourished patient. The role of serum protein measurements in the nutritional assessment of an ill patient with cancer is therefore very limited. Similar limitations apply to the role of immunologic parameters such as total lymphocyte count and delayed cutaneous hypersensitivity. In simple starvation, both of these measures may be decreased and can return to normal with initiation of nutritional support. However, in the cancer patient undergoing chemotherapy, surgery, or radiotherapy or in the midst of an acute illness, these parameters have little determinative value in the assessment of the nutritional state (3,4).

The above parameters have been combined to create numerous nutritional assessment indices. The most extensively studied is the Prognostic Nutritional Index (PNI), which factors measurements of serum albumin, serum transferrin, triceps skin fold, and delayed cutaneous hypersensitivity (5). Buzbey et al. prospectively studied the PNI in patients undergoing gastrointestinal surgery and found that it could accurately stratify patients into high, intermediate, or low risk of developing postoperative complications (6). It must be understood, however, that the index is only as good as the parameters from which it is calculated, and the same limitations outlined above are present in any of these indices.

Subjective Global Assessment

The clinical assessment of the nutritional status has always been used to some extent as part of the general medical history

and physical examination. The validity of a formal clinical assessment of the nutritional status was demonstrated in a landmark study by Baker et al., who developed the Subjective Global Assessment (SGA) (7). The SGA is based on a complete history and physical examination, with special emphasis on six areas: change in weight, dietary intake, gastrointestinal symptoms, functional capacity, physiologic stress, and physical signs of nutritional deficiencies. These data are used to place the patient into one of three groups. Group “A” (normal nutritional status) is made up of those patients without restriction of food intake or absorption, no change in functional status, and stable or increasing weight. Group “B” (mild malnutrition) consists of patients with evidence of decreased food intake and functional status but little or no change in body weight, while those with severe reduction in food intake, functional status, and loss of weight comprise group “C” (severe malnutrition).

The SGA has consistently been shown to be reproducible and reliable in identifying patients at risk for developing complications associated with malnutrition. In the initial study of 59 patients electively admitted to a general surgical ward interobserver reproducibility in classification of the nutritional status was 81%, and in a later study of 202 patients, it was found to be 91% (7,8). Group assignment based on the SGA had prognostic significance on the ensuing clinical course. The initial study by Baker and colleagues showed a significant increase in incidence of infection, use of antibiotics, and length of hospitalization in Group “C” when compared to Group “A” (7). In the follow-up study of 202 patients undergoing gastrointestinal surgery, the rate of septic and nonseptic complications in Group “C” was 7 times greater than in Group “A” (8). However, it must be recognized that although nutritional parameters are used to determine the SGA, the classification may still represent severity of illness rather than specific nutritionally related complications. Only a determination that the classification predicts which patients will respond favorably to nutritional support (with a decrease in complications) can validate the specificity of this technique. Nevertheless, the SGA provides a simple, reproducible, and accurate method to identify patients who are malnourished who could possibly benefit from nutritional support. Clinical assessments similar to the SGA have been shown to be superior to immunologic testing, plasma protein measurements, and bioelectrical impedance in providing a useful evaluation of nutritional status (7–12).

More recently, the SGA has been shown to predict survival and tolerance to chemotherapy among women with ovarian cancer (13,14). It is now considered the preferred method of nutritional assessment for patients with gynecological cancers (15).

PREVALENCE OF MALNUTRITION

The prevalence of malnutrition depends on the tumor type and stage, the organs involved, and the anticancer therapy. Concurrent nonmalignant conditions such as diabetes and intestinal diseases can be important contributing factors.

The prevalence of weight loss during the 6 months preceding diagnosis of cancer was reported from a multicenter cooperative study of patients with 12 types of cancer (16). The lowest frequency (31% to 40%) and severity of weight loss were found in patients with breast cancer, hematologic cancers, and sarcomas. Intermediate frequency of weight loss was found in patients with colon, prostate, and lung cancer (54% to 64%). Patients with cancer of the pancreas and stomach had the highest frequency (over 80%) and severity of weight loss. Approximately 35% of the patients with lung cancer lost more than 5% of their body weight. This underscores the

fact that even if the tumor does not involve the gastrointestinal tract directly, there can be significant weight loss because of systemic and metabolic derangements and loss of appetite. The study did not report on patients with gynecologic malignancies, in whom weight loss can also be very frequent and severe. Other studies revealed that over 40% of patients receiving medical treatment for a variety of cancers were malnourished (17,18). Among surgical patients in a Veterans Administration hospital, 39% of those undergoing a major operation for cancer were malnourished, as judged by either a nutrition risk index or a combination of weight loss and low serum proteins (19). Data on the prevalence and impact of malnutrition in patients with gynecologic tumors mirror the observations in patients with other cancers. In a study of 67 consecutive patients hospitalized with gynecologic cancers at the University of Texas, it was found that 54% of the women were malnourished as determined by the PNI (20). In 1983, Tunca (21) examined the nutritional state of gynecologic oncology patients at time of diagnosis using serum albumin, serum transferrin, immune response, and weight loss. Patients with advanced (stage III or IV) ovarian carcinoma had the highest incidence of severe malnutrition, while those with cancer of the cervix, endometrium, or vulva reported weight loss with no indication of malnutrition from serum markers or immune response testing. Twenty of the 21 patients with advanced ovarian carcinoma were anergic to recall antigens, and the mean levels of all serum markers examined were significantly lower than those found in patients with early (stage I or II) ovarian carcinoma or cancer of the cervix, vulva, or endometrium. Orr et al. (22,23) assessed the degree of protein-calorie malnutrition and evidence of vitamin deficiency in 78 patients with untreated cervical cancer. The incidence of protein-calorie malnutrition as assessed by anthropometrics, serum markers, and immune testing was directly related to tumor stage: 4% in stage I, 20% in stage II and III, and 60% in stage IV disease (22). Two-thirds of patients with untreated cervical cancer were found to have reduced blood levels of at least one vitamin. Mean serum levels of folate, *b*-carotene, and vitamin C at the time of admission were all significantly below control values (23). Similar observations of significant protein-calorie malnutrition were seen in 25 patients with endometrial cancer (24). Using the SGA to study 194 patients with gynecologic cancers, Laky showed that 24% of all patients were malnourished. The prevalence of malnutrition was highest in ovarian cancer (67%) and lowest in endometrial cancer (6%) (15).

SIGNIFICANCE OF MALNUTRITION

The impact of malnutrition on the cancer patient was demonstrated in a report by Warren in 1932 (25). Based on data from autopsies, the conclusion was that cachexia was the leading cause of death in a group of 400 patients with various cancers. More recent studies have confirmed the significant impact of malnutrition on the quality of life and prognosis of the cancer patient. In the aforementioned multicenter, cooperative study of patients receiving chemotherapy (16), those who presented with weight loss at the time of diagnosis had decreased performance status and survival compared with those without weight loss. In a study of patients with limited, inoperable lung cancer, weight loss was a major predictive factor for survival (17). The negative impact of malnutrition was also demonstrated in surgical patients with malignant and benign diseases. Malnourished patients undergoing a major operation were at greater risk for postoperative morbidity and mortality than were well-nourished patients (19,26).

The impact of malnutrition on patients with a primary gynecologic malignancy is striking. While examining the role of total parenteral nutrition (TPN) in their patients, Terada and colleagues noted that those patients who developed major complications such as a fistula, wound infection, pneumonia, renal failure, respiratory failure, or those who died had significantly more weight loss and lower serum transferrin levels at the time of presentation (27). They concluded that these parameters might be of value in predicting clinical outcome in patients requiring nutritional support. This was confirmed in a study by Geisler, who found that in patients with ovarian cancer, those patients who were malnourished had increased postoperative complications. This difference could be mitigated if preoperative nutritional support could reverse the malnutrition (28). Several other studies have confirmed the relationship of malnutrition to poor surgical outcome in patients with primary gynecologic malignancies. Burnett et al. (29) reported that in 92 gynecologic oncology patients requiring colonic surgery, those who were classified as malnourished on the basis of serum markers were significantly more likely to develop major perioperative complications or die. Donato et al. (30) reported that of the 104 patients with ovarian carcinoma undergoing intestinal surgery, those considered to be malnourished on the basis of serum protein measurements and weight loss preoperatively had significantly more infectious complications, while other variables including preoperative bowel obstruction, extent of debulking, number of intestinal procedures, or hand versus stapled anastomosis failed to correlate with the rate of infectious complications (30). Poor nutritional status has been shown to be an independent predictor of prolonged postoperative ICU stay in patients with ovarian cancer (31).

In addition to predicting surgical outcome and perioperative complications, malnutrition is associated with increased neutropenic fever following chemotherapy, prolonged hospital stay, decreased quality of life, and reduced overall survival among women with gynecologic cancers (13,14,15,20,32).

ETIOLOGY OF MALNUTRITION

Cancer can induce a wide variety of derangements in the nutritional status, ranging from generalized malnutrition with severe weight loss and muscle wasting to a single nutrient deficiency. The etiology of malnutrition in the cancer patient is multifactorial. Nutritionally relevant derangements can be induced by the tumor locally (i.e., gastrointestinal obstruction), by malabsorption, or by humoral factors produced by the tumor itself or by reaction of the immune system to the tumor. All modalities of cancer therapy, surgery, radiation, chemotherapy, immunotherapy, and palliative treatments, may be associated with side effects and complications that can impair the nutritional status.

The etiologic factors of malnutrition in the cancer patient, whether caused by tumor or antitumor therapies, can be classified into three major categories: decreased food intake, malabsorption, and metabolic derangements that result in inefficient, wasteful metabolism.

Impaired Food Intake and Absorption

Both tumor and cancer treatment modalities can lead to decreased food intake through direct effects on the gastrointestinal tract or systemic effects leading to anorexia. Obstruction of the gastrointestinal tract can be caused by any gynecologic malignancy through external compression, or more rarely, by direct invasion. Although at times localized obstructions can be relieved surgically or endoscopically, the obstruction due to

peritoneal carcinomatosis often seen in advanced ovarian cancer is particularly difficult to manage surgically. Often, draining gastrostomy with parenteral nutrition (when appropriate) is the only option for providing nutrition and symptomatic relief (33–35).

Tumors can induce anorexia without local involvement of the gastrointestinal tract. The pathophysiology of this phenomenon is not well understood. Norton et al. (36) utilized a model of surgically coupled tumor-bearing and normal rats with parabiotic cross-circulation to show that tumor-induced anorexia is mediated by circulating substances. Tumor-induced impairment of smell and taste has been well described (26,37–40), but the mechanism has not been defined. There is growing evidence that glycoproteins, cytokines, and neuropeptides play an important role in the pathogenesis of cancer cachexia. Bernstein et al. (41,42) demonstrated in a rat model that infusion of tumor necrosis factor (TNF) mimics tumor induced anorexia and these effects are mediated via the area postrema and the caudal medial nucleus of the solitary tract in the central nervous system.

Therapies used for gynecologic malignancies often result in complications that impair nutrient intake and absorption. Surgical interventions can lead to fistulae, short bowel syndrome, infections, and ileus, all of which impair oral intake significantly. In a review of 12 years of colonic surgery in gynecologic oncology patients, the rate for major systemic complications (myocardial infarction, pulmonary embolism, renal failure, sepsis) was 13.7%, and the rate of major bowel complications (abscess, fistulae, hemorrhage, obstruction) was 12.1% (29). Adjuvant radiation and chemotherapy have been shown to increase the incidence of major complications after pelvic exenteration (43).

Radiotherapy can lead to various derangements in the structure and function of the gastrointestinal tract. Damage to the gastrointestinal tract following radiation to the abdomen and pelvis most commonly affects the small bowel, followed by the transverse colon, sigmoid, and rectum. Predisposing risk factors include previous abdominal surgery, pelvic inflammatory disease, thin body habitus, hypertension, and diabetes mellitus (44). In general, a dose of 5,000 rads is the threshold for significant injury. In the acute phase of radiation enteritis, virtually all patients experience anorexia, nausea, and vomiting, which are thought to be mediated by effects of serotonin on the gut (45) and the central nervous system (46). This is followed 2 to 3 weeks later by direct injury to the intestinal mucosa, resulting in diarrhea and mild to moderate malabsorption. Most patients will have complete resolution of these acute symptoms. However, a significant minority of patients who received radiotherapy will experience chronic dysfunction of the gastrointestinal tract (47). There is often a latent period of 1 to 2 years, and possibly as long as 20 years, before the symptoms of chronic radiation enteropathy surface (48,49). In a review of 102 patients with radiation enteritis after treatment for cervical or endometrial cancer, the median time to development of severe symptoms such as obstruction or perforation was 18 months (50).

Chronic radiation enteropathy is characterized pathologically by transmural injury leading to submucosal fibrosis, edema, lymphatic ectasia, and obliterative endarteritis, which can induce colicky abdominal pain, diarrhea, steatorrhea, ulceration, perforation, stricture, and fistula formation (44). Yeoh et al. (51) retrospectively studied the effects of pelvic irradiation given for the treatment of cervical cancer in 30 randomly selected women who had undergone radiotherapy 1 to 6 years earlier. Significant dysfunction of the gastrointestinal tract was detected. Nineteen of the patients had frequency of bowel movements, bile acid absorption, and vitamin B₁₂ absorption outside of the control range. The authors concluded that abnormal gastrointestinal function is essentially an inevitable long-term complication of pelvic irradiation (51). Huaebye and colleagues (52)

prospectively studied the gastrointestinal motility patterns in 41 patients with chronic abdominal complaints after radiotherapy for gynecologic cancer. Impaired fasting motility was found in 29% of patients, and motor response after a meal was attenuated in 24%. Postprandial delay of the migrating motor complex was found to be an independent predictor of malnutrition as assessed by weight loss and serum albumin. Impaired motility of the small bowel, therefore, is a key factor in the symptoms experienced by patients with chronic radiation enteropathy (52). Chronic radiation enteritis predisposes to numerous secondary complications. Danielsson et al. (53) studied 20 patients with chronic or intermittent diarrhea occurring in women 2 or more years after receiving radiotherapy for gynecologic tumors. Bile acid malabsorption was detected in 65% of patients, while evidence of bacterial overgrowth on D-xylose or cholyl-glycine breath tests was found in 45%. Treatment with bile acid binders or antibiotics resulted in a significant decline in the number of daily bowel movements. The authors concluded that treatment of these secondary complications of radiation-induced enteropathy can offer significant symptomatic relief. In 47 patients with gynecologic malignancies who had gastrointestinal complaints lasting more than 4 months after radiotherapy, Kwitko et al. (54) found 19 partial small bowel obstructions, 11 cases of malabsorption, and 5 fistulae. The mortality from radiation damage to the small bowel in this report was 32%. More recently, Boland reported on a 25-year experience with postresection short bowel syndrome secondary to radiation therapy. The majority of the cases were in women who received pelvic radiation for gynecologic cancers (55). Improved fractionation of radiotherapy and protective shielding of the intestine where possible have reduced these complication rates (56). More recent studies of patients who received radiation therapy for uterine cancer found the prevalence of significant chronic radiation enteritis to be approximately 4% (57).

Chemotherapy is often associated with decreased food intake. Mucositis and diarrhea are commonly seen during therapy with cytotoxic agents that affect the replicating cells of the intestinal mucosa, such as 5-fluorouracil, methotrexate, and bleomycin. The vinca alkaloids can cause ileus and constipation mediated by toxic effects on gastrointestinal neural pathways, while cisplatin and nitrosoureas are highly emetic (58,59). Significant nausea, vomiting, stomatitis, and diarrhea occur in 15% of patients receiving intravenous taxol and 55% in those receiving the drug orally (60). In addition to direct effects on the GI tract, chemotherapy in women with gynecologic cancers has significant effects on olfactory and gustatory function, leading to reduced appetite and weight loss (61).

The psychological impact of a malignancy and its associated therapies can also lead to decreased nutrient intake. Depression is a frequent cause of anorexia in this population, with up to 58% of cancer patients having depressive symptoms and 38% meeting criteria for major depression (62).

Metabolic Derangements

Even with normal nutrient intake patients with cancer are at risk for malnutrition due to inefficient nutrient utilization and wasteful metabolic pathways. Compared to simple starvation, cancer cachexia is associated with altered metabolism of carbohydrates, fat, protein, vitamins, and minerals. Therefore, in order to optimize nutritional support in the cancer patient, it is imperative to consider metabolic derangements along with problems of ingestion, digestion, and absorption.

Increase in basal energy expenditure has been reported in many but not all studies of patients with malignancy (63–69). In patients with newly diagnosed small cell lung cancer, Russel et al. (67) showed a mean increase of 37% in basal energy expenditure, which fell substantially in those who responded to chemotherapy. Similar findings have been reported for gastric

cancer (64) and sarcoma (70). Elevated basal energy expenditure will drop after tumor resection (71). There are limited data on the metabolic rate in patients with gynecologic cancers (69). Dickerson et al. (72) used indirect calorimetry to determine the resting energy expenditure in 31 patients with ovarian cancer and 30 patients with cervical cancer. Fifty-five percent of those with ovarian cancer were found to be hypermetabolic (BEE >110% predicted by the Harris-Benedict equation), while only 13% of patients with cervical cancer were hypermetabolic. These differences could not be explained by differences in the extent of disease, nutritional status, body temperature, or nutrient intake.

Abnormalities in carbohydrate metabolism in cancer patients include glucose intolerance and peripheral insulin resistance (73–76). These most often become apparent in the patient with advanced metastatic cancer found to have hyperglycemia, which is refractory to high-dose insulin infusion (76,77). In comparison, in simple starvation, patients are most often euglycemic or hypoglycemic. The hyperglycemia seen in cancer patients is exacerbated by increased hepatic gluconeogenesis. Shaw et al. (78) showed that this increase in glucose production is correlated with tumor burden and decreases after tumor resection. An increase in wasteful metabolic cycles such as the Cori cycle likely also contributes to altered glucose metabolism in cancer patients. Tumor cells produce lactate, which is used as substrate for gluconeogenesis in the Cori cycle and reconverted to glucose. For each cycle, there is a net loss of four high-energy phosphate bonds, leading to a large amount of energy wasted in this futile cycle. Though initial studies showed that the increase in the Cori cycle had a large contribution to increased energy expenditure in patients with metastatic disease and weight loss, subsequent studies show that an increase in the Cori cycle has only a minor role in alterations of glucose metabolism. There is ongoing research identifying other futile cycles (79).

Lipid metabolism may also be abnormal in patients with a malignancy. There is often increased lipolysis with weight loss, and this leads to a decrease in fat mass, which can be out of proportion to the loss of lean body mass (75,80). In addition, patients with cancer are often hyperlipidemic, and this may be mediated by TNF- α (81). In contrast to normal homeostasis, cancer patients fail to suppress lipolysis with glucose infusion (78). Several causes of increased lipolysis have been proposed, including decreased food intake, stress response to illness with adrenal medullary stimulation and increased circulating catecholamine levels, insulin resistance, and release of lipolytic factors produced by the tumor itself or by myeloid tissue cells (82). One such factor has been well characterized (83). Lipid mobilizing factor (LMF), a 24-kDa glycoprotein produced by tumors has been shown to stimulate increased lipid mobilization from adipocytes (84). LMF is thought to act through binding of β -adrenergic receptors and subsequent upregulation of mitochondrial uncoupling proteins (85,86). Animal studies have shown that LMF causes loss of body weight (specifically a loss of body fat), which is independent of caloric food intake (87). The activity of LMF in the urine and serum of cancer patients has been shown to correlate with the degree of weight loss (88) and tumor burden (89). In addition to its effect on lipid metabolism, there is preliminary evidence that LMF may protect tumor cells from free radical toxicity and may therefore make tumors less responsive to certain chemotherapeutic agents that induce oxidative damage (90).

High total body protein turnover, with increased synthesis and catabolism, characterizes the alterations of protein metabolism seen in cancer patients (91,92). This results in depletion of muscle mass and loss of nitrogen, and contrasts with the adaptive decrease in protein turnover seen in patients with uncomplicated starvation (93). Total parenteral nutrition given to patients with cancer will result in gains of weight and body fat, net gains

of total body nitrogen, but no suppression of the high protein flux (92,93). The predominant mechanism of muscle protein loss in cancer patients is an ubiquitin-associated pathway (94). In this pathway polyubiquitin chains are attached to proteins, which are then recognized and degraded by a proteasome complex. This pathway is regulated, in part, by proteolysis-inducing factor (PIF). PIF is a 24-kDa glycoprotein produced by human tumors and was found in the urine of cancer patients who were losing weight, but not in the urine of cancer patients who were maintaining their weight. In fact, PIF expression directly correlates with the severity of weight loss. There are multiple mechanisms by which PIF induces weight loss. PIF has a direct effect on skeletal muscle by decreasing protein synthesis and increasing protein degradation by upregulating the ubiquitin-proteasome dependent pathway. PIF also increases the expression of proinflammatory cytokines (i.e., interleukin-6 and -8), which independently cause weight loss, and induces the shedding of syndecans (transmembrane proteoglycans), which has been shown to be related to increased metastases and mortality (79,95). Effective treatment of the underlying cancer has been shown to reverse ubiquitin-dependent proteolysis of skeletal muscle (96). Better understanding of this process holds the promise of improving therapy to attenuate the loss of protein seen in patients with cancer (97).

Cytokines play an important role in inducing the metabolic derangements seen in the cancer patient (69). They mediate increased energy expenditure, whole body protein turnover, rise in serum triglyceride levels, and high glycerol turnover (25,98). TNF can be detected in the serum of cancer patients (99), and in animal models, it causes protein wasting, depletion of body fat, and anorexia (100,101). High serum levels of interleukin-1 and interleukin-6 are also present in patients with advanced cancer and cachexia. Interventions to downregulate these cytokines result in improved appetite, body weight, and quality of life (102).

The combined effects of these wasteful and inefficient alterations in metabolism make it difficult to restore nutritional status in the patient with cancer and cachexia despite the use of specialized nutritional support. This is in contrast with what is seen in patients with uncomplicated starvation who exhibit changes in metabolism, which act to conserve energy and body tissues, and in whom nutritional support is highly efficacious in reversing the effects of malnutrition.

NUTRITIONAL THERAPIES

There are four types of nutritional therapies: parenteral nutrition, enteral nutrition, oral dietary therapy, and drug therapy aimed at improving appetite and food intake. Depending on the patient's condition, nutritional support in the cancer patient has two distinct objectives: (a) provision of nutrition during anticancer therapies to counteract their nutritionally related side effects and improve outcome following these therapies and (b) support in patients with long-term or permanent severe impairment of the gastrointestinal tract. In these patients, nutritional support may be required for indefinite periods of time. Results of numerous clinical trials support the use of nutritional support only in limited situations during anticancer therapies. In the group with prolonged gastrointestinal failure, nutritional support may be a lifesaving therapy because patients could die of starvation without TPN or enteral feeding.

Total Parenteral Nutrition

TPN is an effective method for delivery of nutrients directly into the blood, and thus overcomes the major causes of cancer-induced

weight loss, including decreased food intake and dysfunction of the gastrointestinal tract. Survival for more than 20 years in patients nourished exclusively by TPN clearly demonstrates the life-saving role of this method of nutritional support. Initially, it seemed logical that TPN would be an effective adjuvant therapy for most cancer patients undergoing radiation therapy, surgery, or chemotherapy because of the accompanying cachexia and inability to eat adequately. Randomized studies, however, have shown that TPN only benefits a select subgroup of cancer patients during anticancer therapy.

Efficacy

In patients receiving chemotherapy with or without radiation therapy, TPN can lead to improvements of several nutritional parameters. Both body weight and body fat increase (93). Deficits of specific vitamins, minerals, and trace elements can be corrected, and hydration status can be improved (93,103). TPN, however, does not alter many of the metabolic derangements encountered in the cancer patient. Increased glucose oxidation and turnover persist (78,104), as does muscle proteolysis (105,106) and increased lipolysis (107). Finally, TPN does not stop the overall losses of body nitrogen (108). The relevant issue for the clinician is the effect of TPN on the morbidity and mortality associated with cancer therapy and whether TPN can allow more intense therapy as was initially hoped. Numerous randomized trials have examined this issue. Studies of patients undergoing chemotherapy for carcinoma of the ovary (33), lung (109,110), colon (108), testes (111), lymphoma (112), and other tumors (113) have been conducted. However, the patients in these studies were largely unselected. Many were not malnourished and others had adequate oral intake with intact gastrointestinal function, making intravenous nutrition unnecessary, futile, and potentially harmful. Numerous meta-analyses concluded that nondiscriminatory use of TPN in patients undergoing chemotherapy offers no improvement in mortality, response to chemotherapy, or reduction in treatment associated complications (114–116). This conclusion was echoed in a consensus statement from the National Institutes of Health, the American Society for Parenteral and Enteral Nutrition, and the American Society for Clinical Nutrition (117). The improvement in nutritional parameters afforded by TPN in patients receiving chemotherapy is not necessarily translated into improved clinical outcome. Thus, the routine use of TPN in these patients is not indicated.

There are circumstances, however, in which nutritional support with parenteral nutrition should be considered. These include prevention of the effects of starvation in a patient unable to tolerate oral or enteral feedings for a prolonged period of time (usually more than 7 to 10 days), maximization of performance status in a malnourished patient prior to chemotherapy or surgery, and in patients undergoing bone marrow transplantation (118). TPN may have a stimulatory effect on tumor cell cycle kinetics (119). It was hoped that this effect would induce improved tumor response to cell cycle-specific chemotherapy. Conclusive proof of such a response remains elusive.

A few randomized studies have examined the use of TPN in patients receiving radiotherapy to the abdomen and pelvis (120–123). These studies did not show any clear benefit from the routine administration of TPN.

The role of TPN in the perioperative period has been extensively studied (19,124–128). In an early study by Mueller et al. (128), 10 days of preoperative TPN was associated with nutritional improvement and significant reduction in major postoperative complications and mortality. These impressive results have not been confirmed in subsequent studies. At Memorial Sloan-Kettering Cancer Center, a prospective study of 117 patients undergoing curative resection for pancreatic cancer randomized to receive TPN or intravenous fluids in the postoperative period

showed no benefit from routine use of postoperative TPN (129). The group receiving TPN had a significant increase in postoperative infectious complications. The largest prospective randomized trial investigating the role of TPN in the perioperative setting was the Veterans Administration Cooperative Study (19). In this study, 395 patients were randomized to receive 7 to 15 days of preoperative and 3 days of postoperative TPN, or oral feeding plus intravenous fluids. TPN did not improve morbidity or 90-day mortality. However, subgroup analysis showed that patients considered to be severely malnourished had fewer infectious complications if they received TPN. The authors concluded that the routine administration of preoperative TPN should be limited to patients who are severely malnourished, unless there are other specific indications.

Randomized studies specifically examining the role of perioperative TPN in patients with gynecologic malignancies are lacking. In a report by Terada (27), perioperative parenteral nutritional support was given to 84 of 99 patients. There were no major complications attributed to TPN, but 27% of the patients experienced minor complications: 11% due to central line placement or catheter sepsis, 2% due to fluid overload, and 13% had metabolic complications. There was no report on overall perioperative morbidity or mortality in comparison to patients who did not receive perioperative TPN.

These data and others provided the basis for a consensus statement from the National Institutes of Health, the American Society for Parenteral and Enteral Nutrition, and the American Society for Clinical Nutrition regarding the use of perioperative TPN, which states the following: (a) 7 to 10 days of preoperative TPN in a malnourished patient with gastrointestinal cancer results in a 10% reduction in postoperative complications; (b) routine use of postoperative TPN in malnourished surgical patients who did not receive preoperative TPN results in a 10% increase in complications; (c) if by postoperative day 5 to 10 a patient is unable to tolerate oral or enteral feedings, then TPN is indicated to prevent the adverse effects of starvation. This panel, however, cautioned that in the majority of studies looking at perioperative TPN, the amount and type of parenteral nutrition given was not optimal, and often patients were given excess calories. Therefore, the results may differ with the provision of relatively hypocaloric formulas (117). It is reasonable to extend these recommendations to the gynecologic oncology patient undergoing surgery (Table 32.1).

Composition of TPN Solution

Once the decision to proceed with parenteral nutritional support is made, access to a large bore central vein should be obtained. This allows the use of calorically dense, hypertonic solutions,

which are often necessary in severely ill patients who may have restriction on the amount of intravenous fluids they can receive. The solution must provide the protein and caloric needs, fluid, minerals, trace elements, and vitamins. Although indirect calorimetry and nitrogen balance can be used to determine energy and protein requirements, they are too costly and cumbersome for routine use. There are numerous formulas, charts, and tables that can provide estimates of protein and calorie requirements. Estimates of nutrition requirements are based on weight and adjusted for the degree of physiologic stress encountered by the patient. Generally, patients require approximately 30 Kcal/kg nonprotein calories, 1 g/kg amino acids, and about 2,000 mL of fluid. As illness severity increases and organs' functions change, adjustments may be required. Nonprotein calories can be provided as dextrose or lipid, and the relative amounts of these should also be individualized. Lipids provide 9 Kcal/g compared to 3.4 for dextrose (in dextrose solutions, glucose is present as glucose-monohydrate; hence, a gram contains less than 4 Kcal). Lipid calories are particularly useful in patients who have high caloric requirements but cannot tolerate a large fluid load. In addition, lipids are useful in patients with severe pulmonary or hepatic dysfunction as glucose metabolism produces more carbon dioxide, which can add to the burden of the ailing lung and can lead to fatty infiltration of the liver. Up to 60% of caloric requirements can be provided as lipid, but serum triglyceride levels must be monitored closely. Appropriate electrolyte content of TPN solutions is of critical importance. The amounts have to be tailored to the patient's requirements and organ's function. Care must be taken to prevent potentially fatal hypokalemia or hypophosphatemia (particularly in the patient with severe weight loss), which can be precipitated by insulin induced transport of the minerals to the intracellular space when inadequate amounts are given. Other electrolyte disorders, such as cisplatin-induced hypomagnesemia and SIADH, are common in the patient with gynecologic malignancy and must be addressed when ordering TPN. The TPN solution must also contain vitamins, minerals, and trace elements. Typically, these are available as standard commercial combination products. However, certain patients require specific modifications. For example, a patient with persistent diarrhea requires zinc supplementation in excess of the amounts present in standard trace element solutions.

Complications

Complications associated with TPN can be classified as catheter related, metabolic, or infections. Catheter complications most often occur during placement of a central venous catheter and include pneumothorax, hemothorax, arterial injury, and hematoma. These can all be minimized when the procedure is performed by an experienced physician (130). Cobb et al. (131) reported a 3% incidence of pneumothorax, arrhythmia, thrombus, or bleeding during 523 intravenous catheter placements. A more recent study of subcutaneous peripheral infusion ports in women with gynecologic malignancies demonstrated a thrombosis rate of 26% during a mean follow-up of 105 days. The authors concluded that other types of vascular access devices may be preferable in this patient population (132).

Metabolic derangements are frequently encountered during support with TPN, and the prescribing physician must be well versed in the pathophysiology of these disorders. Hyperglycemia is the most common abnormality (130), and if not corrected, can lead to an osmotic diuresis, dehydration, acidosis, and hyperosmolar coma. One metabolic complication that deserves special mention is the "refeeding syndrome." In chronically ill patients with severe malnutrition, there is often a depletion of total body phosphorus and potassium. The phosphorous deficits may be masked by increased renal phosphorous absorption designed to maintain normal serum levels. When nutritional support is

Table 32.1 Indications for TPN in Hospitalized Patients with Gynecological Cancers

Perioperative	• 7–10 d preoperatively in a malnourished patient (who cannot be fed enterally) • Postoperative complications that prevent oral or enteral intake for more than 7–10 d • Enterocutaneous fistula • No indication for routine use
During radiation or chemotherapy	• Maximization of performance status prior to therapy in a malnourished patient who cannot be fed enterally • Severe persistent (more than 7–10 d) mucositis, diarrhea, ileus, or emesis • No indication for routine use
General	• After 7–10 d of inability to tolerate oral or enteral feeding due to any cause

initiated, the infusion of a large glucose load with subsequent surge in insulin leads to increased cellular uptake of phosphorous and potassium, which may induce severe life-threatening hypokalemia and hypophosphatemia (133,134). These disorders cause widespread tissue and organ dysfunction, including muscle weakness, rhabdomyolysis, heart failure, cardiac arrhythmias, and respiratory failure, and may result in death in extreme cases (134). Therefore, in patients with evidence of severe undernutrition, nutrition support should be initiated with small amounts of dextrose calories, supplemental phosphorous and potassium, and careful monitoring of serum phosphorous and electrolytes.

TPN has been associated with cholestatic liver disease, as well as fatty infiltration of the liver and glycogen deposition. These abnormalities have been attributed to infusion of excessive glucose calories, imbalance of amino acids, and rarely, fatty acid deficiency (135). Elevation of serum transaminases may occur, but it is generally mild (135,136). Severe liver dysfunction in adult TPN recipients is rare and requires a search for causes other than TPN.

Infections are particularly serious complications in patients with malignancy receiving TPN. In an evaluation of seven studies comparing TPN plus chemotherapy to chemotherapy alone, Klein and Koretz found four studies that showed an increase in infectious complications in patients receiving TPN (122). A meta-analysis by the American College of Nutrition showed a fourfold increase in infections when patients receiving chemotherapy were given TPN (114). In a prospective, randomized study of TPN following pancreatic resection, recipients of TPN had significantly more infectious complications (129). Data from a VA randomized cooperative study showed that patients with mild to moderate malnutrition given perioperative TPN had increased rates of infections, while those with severe malnutrition developed significantly fewer infections when supported with TPN (19). Infectious complications are related to both central venous catheters and a variety of sites (wound infection, abscess, and pneumonia).

Home TPN

Long-term TPN in the home can be a lifesaving treatment in an appropriately selected group of patients. It is clear that cancer patients who have had severe gastrointestinal injury, such as massive intestinal resection or severe radiation enteritis, and in whom the cancer has been cured or is well controlled, benefit from long-term TPN at home (137). Survival rates and TPN-related complications in such patients are comparable to those seen in patients with benign diseases (Crohn's disease, intestinal necrosis) who require home TPN. Among patients with widely metastatic disease and poor prognosis, home TPN offers very limited benefit (106). Only 15% of such patients survive longer than 1 year on home TPN (52). Recently developed techniques for placing feeding tubes make it possible to hydrate and feed patients enterally, even in the presence of gastrointestinal obstruction (118), and thus obviate the need for home TPN in patients with upper gastrointestinal tract dysfunction. In terminally ill patients, TPN should be avoided. The concern that such patients should not be "starved to death" is not a justification for TPN. A recent uncontrolled study of terminally ill cancer patients hospitalized at a long-term care facility suggested that these patients did not experience hunger or thirst, and that in those who experienced such symptoms, small amounts of food alleviated the symptoms (138). In such patients, the utilization of TPN either in the home or at health care facilities cannot be justified.

For patients with inoperable bowel obstruction due to metastatic ovarian cancer, predicting which patients will benefit from home TPN can be difficult (139). In a review of 9,897 days of

home TPN administered to 75 patients with various cancers and intestinal obstruction, it was shown that a Karnofsky performance status greater than 50 at the initiation of TPN could accurately predict which patients would have improved quality of life while on home TPN. The authors concluded that home TPN should be avoided if the performance status is below this level (140). In addition, patients with a life expectancy of less than 2 to 3 months will not benefit from home TPN (106,140). In a study from Yale-New Haven Hospital of 17 patients with inoperable bowel obstruction due to malignancy, patients with ovarian cancer had the shortest survival (39 days) compared to patients with colon cancer (90 days) and appendiceal cancer (184 days) (141). Therefore, only a highly selected minority of patients with inoperable bowel obstruction can potentially benefit from home TPN. A recent study from Brown University evaluated 55 patients with terminal ovarian cancer and found the use of TPN conferred a median survival benefit of 4 weeks (142). Currently, the best selection criteria for such patients are a fair or better performance status and the potential for further antitumor therapy (Table 32.2).

Enteral Nutrition

Enteral feeding delivers a liquid-nutrient formula into the gastrointestinal tract through tubes placed into the stomach or small intestine. As in oral feeding, an adequately functioning small intestinal mucosa is required for absorption of nutrients. Enteral feeding can overcome many difficulties encountered in patients with a wide variety of gastrointestinal tract dysfunction. A proximal gastrointestinal obstruction can be bypassed; tubes can be placed distal to obstructions as far as the jejunum, and thus circumvent obstructing lesions of the oral cavity, esophagus, stomach, duodenum, or proximal jejunum (143,144). The liquid-nutrient formula can be delivered as a slow, continuous infusion, thus maximizing absorption by a limited intestinal surface, which can be overwhelmed by the higher volume delivered during oral feeding. Such an approach may be useful in patients with radiation enteritis, short bowel syndrome (with adequate remaining short bowel, usually 3 to 4 ft), or partial obstruction of the bowel.

Route of Administration and Nutrient Formula

Short-term (<2 weeks) access to the gastrointestinal tract can be obtained through nasogastric or nasoenteric tubes. Patients requiring longer nutritional support should have a gastrostomy or jejunostomy tube placed endoscopically, radiologically, or surgically. In comparison to nasal tubes, gastrostomy or jejunostomy tubes are wider (15 to 24 Fr) and therefore less likely to be obstructed by medications or nutrient solutions. In addition, they are fixed in the stomach or the upper intestine and do not migrate into the esophagus. Thus, the risk of aspiration is considerably decreased (143). These tubes are more comfortable and aesthetically pleasing (145). These benefits were demonstrated in a randomized study of patients after an acute dysphagic stroke, which showed patients fed with a gastrostomy

Table 32.2 Indications for Home TPN in Patients with Gynecological Cancers

- Severe chronic radiation enteropathy
- Short bowel syndrome
- Persistent enterocutaneous fistula
- Selected patients with obstruction due to peritoneal carcinomatosis. (Selection based on performance status and potential for further chemotherapy)

tube had more optimal provision of nutrients, achieved a better nutritional state, and had less mortality than those fed with nasogastric tubes (146). Patients with gastrostomy tubes have been shown in prospective studies to receive over 90% of prescribed feedings compared to only 55% in patients fed through nasal tubes. These differences are largely attributed to nasogastric tube dislodgment (147). In a randomized study of 33 women with gynecologic malignancies, enteral feedings through a needle catheter jejunostomy maintained postoperative nutrition as measured by serum transferrin levels and was associated with few complications (148). The authors concluded that women with gynecologic cancers should have a jejunostomy placed at the time of operation if it is anticipated that long-term nutritional support will be required.

Endoscopically placed percutaneous gastrostomy tube (PEG) has become the procedure of choice for placement of enteral feeding tubes because of its ease, safety, and the ability to perform it on an outpatient basis. Percutaneous jejunostomy (PEJ) tubes can also be placed endoscopically (144). PEJs allow for continued enteral feeding in patients with gastric resection, gastric outlet obstruction, or gastroparesis. Major complications (bleeding, peritonitis, abdominal wall abscess, colonic perforation, and aspiration) from PEG and PEJ placement are rare, occurring in 0 to 2.5% of patients, while minor complications (wound infection, tube migrations, or leak) are seen in 5% to 15% (70,144,149,150). More than 100 different enteral feeding formulas are currently commercially available (151). They are designed to provide complete nutrition, single nutrients, or only fluids and electrolytes. Formulas differ in protein concentration, calories, osmolality, and percentage of nonprotein calories delivered as carbohydrates or fats. Enteral feeding formulas, which provide 1,500 to 2,000 Kcal/day, normally contain all the necessary nutrients including proteins, vitamins, minerals, and trace elements. In addition, there are disease-specific formulations for patients with diabetes or hepatic, renal, or pulmonary dysfunction. The choice of formula should be individualized, and it often helps to minimize problems such as diarrhea, bloating, or hyperglycemia (143).

Enteral solutions may be administered by either bolus feedings or continuous infusion (143). Bolus feeding is possible when the tip of the feeding tube is in an intact stomach. Up to 500 mL of a feeding formula can be infused over 10 to 15 minutes by a syringe or gravity into the stomach. The pyloric sphincter regulates flow into the duodenum. All bolus feedings should be done with the patient sitting upright to minimize the risk of aspiration. When the tip of the feeding tube is distal to the pylorus, continuous feeding must be employed to avoid abdominal distention and diarrhea. Rates as high as 150 mL/hour are generally well tolerated (143).

Efficacy

Data from randomized trials examining the efficacy of enteral nutrition given as an adjuvant therapy in patients receiving chemotherapy for a variety of cancers have failed to demonstrate a clear benefit in terms of survival or response to treatment (152–156). The validity of the conclusions of these studies, however, is limited by their small size and poor design. Similar difficulties plague the studies examining the role of standard enteral nutrition in the perioperative period (157–160). While recent data examining early (postoperative day 1) enteral feeding in patients following resection of an upper gastrointestinal tract tumor showed improved protein metabolism, there is no evidence that this translates into improved clinical outcome (161). In a prospective, randomized study of early enteral feeding in 195 patients after resection of upper gastrointestinal malignancy there was no proven benefit. Complication rates, mortality, and length of hospital stay were not affected by early postoperative enteral feedings (162). Therefore, routine use of enteral nutrition

support in patients receiving chemotherapy or undergoing operations for cancer cannot be justified. Accepted indications for enteral nutrition in cancer patients include (a) obstruction of the upper digestive tract in those in whom enteral access can be safely obtained beyond the site of obstruction, (b) the presence of chronic malnutrition due to inadequate oral intake, and (c) perioperative support of the malnourished patient (163).

Complications

Enteral nutrition is generally safe if careful attention is paid to the following: (a) choice of an appropriate formula, (b) infusion into an appropriate portion of the gastrointestinal tract, (c) use of the correct infusion method, and (d) an ongoing clinical and metabolic monitoring of the patient. The most serious complication of enteral feeding is aspiration, which occurs in 1% to 32% of patients (152,164,165). The risk is minimized by keeping patients upright during bolus feedings and using jejunal feedings if there is predisposition for aspiration, gastroparesis, or an impaired gag reflex. Diarrhea is reported in 5% to 30% of patients receiving enteral nutrition (166). While the diarrhea may be related to underlying disorders of the gastrointestinal tract, such as radiation enteritis or short bowel syndrome, a commonly overlooked cause is medications. Patients on enteral feeding often receive magnesium-containing antacids or antibiotics, both of which may induce diarrhea. Metabolic complications include dehydration, azotemia, hyperglycemia, and hyperkalemia. These are usually due to the patient's underlying disease and can be avoided with the choice of the proper formula and careful monitoring.

Home Enteral Nutrition

Home enteral nutrition (HEN) is increasingly being used to provide nutrients and fluids outside the hospital. Cancer is the most common indication for its use and accounts for 42% of all patients receiving HEN (137,143). It is a safe therapy in patients with cancer, with only a 0.4% annual rate of complications requiring hospitalization (167). The overall 1-year survival for cancer patients on HEN is 30%. However, in patients with cancer of the head and neck who have been successfully treated, HEN has provided good nutrition for periods exceeding 7 years (70,143). Regular medical follow-up is essential to ensure appropriate functioning of the feeding tube and optimization of the nutrition regimen. This form of therapy is useful in patients with gynecologic malignancies with upper gastrointestinal tract obstructions that cannot be treated surgically.

Oral Dietary Therapy

Patients who are able to eat but have impairment of the gastrointestinal tract or have special metabolic requirements may benefit from a specialized oral dietary therapy. Often, this may obviate the need for more costly and complex interventions such as parenteral nutrition. In oral dietary therapy, the regular diet is modified based on the pathophysiologic changes induced by the underlying disorder, with the goal of providing the most optimal nutrition possible (158). When the main problem is inadequate food consumption, various commercial oral supplements can be used, but usually for only short periods because of taste fatigue. Some preparations provide complete nutrition, while others are intended to supplement deficits of specific nutrients. Problems common in patients with gynecologic malignancies, such as partial small bowel obstruction, chronic radiation enteritis, and short bowel syndrome, may all be amenable to dietary therapies. In partial small bowel obstruction or motility dysfunction, a diet comprised of frequent, small, calorically dense meals with minimal

amounts of fiber is indicated. Patients with radiation enteritis should receive a low-fat, low-fiber, and lactose-free diet. Dietary management of short bowel syndrome patients includes frequent small meals, limitation of fiber, lactose, and simple sugars, taking liquids separately from meals, and supplementation of calcium and zinc orally and magnesium and vitamin B₁₂ parenterally.

Bye et al. (168) conducted a prospective, randomized trial of a low-fat, low-lactose diet in 143 women with gynecologic malignancies undergoing radiation therapy. The intervention group had significantly less diarrhea. Diarrhea in the control group correlated with increased fatigue and decreased physical function. The authors concluded that diet intervention during radiotherapy reduced the severity of diarrhea, influenced patients' ability to cope with diarrhea, and gave them more control over their situation.

The successful implementation of prescribed diets depends to a large extent on a dietician converting the prescribed diet to a meal plan and working with the patient to implement it. In a prospective, randomized study of 57 patients undergoing chemotherapy for ovarian, breast, or lung cancer, those who received intensive dietary counseling had improved long-term food intake (169). Similar data have been demonstrated in cancer patients undergoing radiotherapy (170) and in patients with acute leukemia undergoing induction chemotherapy (171).

Pharmacologic Agents

Agents that will reverse the wasting seen in advanced cancers have long been sought to complement or replace the provision of nutrients via the oral, enteral, or parenteral route. Hormones, appetite stimulants, and most recently, cytokine antagonists have been examined. Studies of growth hormone (172,173) IGF-I alone (173) or IGF-I with insulin (174) in cancer bearing rodent models showed significant attenuation of tumor-induced weight loss. In human clinical trials, these agents provided modest gain in weight but no improvement in quality of life or other benefits (175).

Hormones

Ghrelin, a potent orexigenic peptide hormone produced by the stomach has been shown to increase appetite and caloric intake in normal individuals and in animal models of cancer cachexia. It was therefore hypothesized that ghrelin may be an effective treatment for cancer-induced cachexia. One small randomized study showed that intravenous ghrelin led to a marked increase in energy and caloric intake, with no side effects (176). There was concern that its use would be limited by its promotion of cellular proliferation and invasion of certain types of cancer, but a randomized, placebo-controlled, double-blind, double cross-over study demonstrated that ghrelin was safe and well tolerated, but unfortunately did not show any change in nutritional intake (177).

Appetite Stimulants

Anabolic steroids have no proven efficacy in treating cancer cachexia. In a murine model, administration of norandrolone propionate resulted in weight gain, but this was largely due to fluid retention (178). In human trials, steroids produced transient improvement of nutritional parameters and appetite, but continued use is associated with negative nitrogen balance, net calcium loss, glucose intolerance, and immunosuppression (175).

Megestrol acetate is a progestational agent that has been shown to improve appetite and ameliorate weight loss in numerous, but not all, studies of patients with cancer and cachexia (175). Doses in these studies ranged from 160mg/day - 1200mg/

day, and maximal weight gain was generally seen within 8 weeks. However, the change in weight is largely due to increased adipose tissue and edema (179). Nevertheless, improvement in quality of life has consistently been demonstrated in several large prospective studies in patients with cancer cachexia treated with megestrol acetate (180,181). It is generally well tolerated but can exacerbate underlying diabetes mellitus, increase thrombotic risk, and rarely lead to adrenal suppression. Dronabinol, a marijuana derivative, has shown some promise in small studies, improving appetite and causing weight gain; however, large randomized trials are lacking (175).

Cytokine Inhibitors

Inhibitors of cytokines involved in cancer cachexia and anorexia have the potential to be potent agents in the treatment of malnutrition in cancer. Monoclonal antibodies against TNF lead to improved food intake and diminished loss of protein and fat in murine models of cancer cachexia (167). Similar data are available for anti-IL-6 (182,183) and anti-IFN- γ (184). Suramin, a direct IL-6 receptor antagonist, decreased several key parameters of cachexia in tumor-bearing mice (185). In a recent study from Japan, a novel inhibitor of IL-1 and TNF- α showed that direct injection of the drug into tumor did not alter tumor growth but did result in attenuation of loss of body weight and epididymal fat in tumor-bearing mice (186). Human studies utilizing the anticytokine approach are limited. Pentoxifylline and thalidomide have been shown to inhibit TNF- α , but only thalidomide improved weight loss associated with AIDS and tuberculosis (187). Interestingly, recent data showed that the clinical anticachexia effects of megestrol acetate are due, at least in part, to the inhibition of cytokines (102) (Table 32.3).

Drugs to Relieve Symptoms

The use of medications to relieve cancer- or treatment-related symptoms that impair oral intake is an important adjuvant to nutritional support in these patients. For example, optimal antiemetic therapy can now adequately control acute and delayed emesis in 70% to 90% of patients (188). Despite this, the incidence of chemotherapy-induced nausea and emesis is underestimated by oncologists and nurses (189). This highlights the importance of a careful history and review of systems when completing a nutritional evaluation of a cancer patient. Many cancer patients assume that nausea and vomiting are normal during treatment and will not report it as a problem unless specifically asked.

ETHICAL CONSIDERATIONS

Prior to the advent of enteral and parenteral feedings, the inability to receive nutrients through oral intake inevitably led to wasting and death. Therefore, in the majority of patients, the natural history of cancer led to death because of dehydration and starvation (190). In patients with potentially curable or stable disease, nutritional support, when indicated, is an important and often critical part of the overall treatment plan. On the other hand, the role of nutritional support in the terminally ill is a subject filled with ethical and legal dilemmas. These problems come to light when the wishes of the patient or the patient's representative are not in agreement with the recommendations of the physicians. For example, a patient may wish to forego nutritional support despite recommendations that such a therapy should be given. Alternatively, patients or their representatives may want to initiate or continue TPN even after all anticancer therapies have failed and the patient is in a terminal state. Two general principles apply: in the first case, autonomy, and in the second, medical futility.

Table 32.3 Pharmacologic Agents Used for the Treatment of Cancer Cachexia and Anorexia

Class of Agent	Example	Efficacy	Adverse Effects
Hormones	Insulin, IGF, GH	Attenuation of tumor-induced weight loss, <i>no</i> improvement in survival or quality of life demonstrated	Hypoglycemia, Hypokalemia
Anabolic Steroids	Oxandrolone, Nandrolone	Transient improvement in appetite	Fluid retention, Net loss of calcium and nitrogen, Hyperglycemia, Immunosuppression
Progestational Agents	Megestrol Acetate	Improved appetite, weight, and quality of life	Weight gain is mostly due to fluid retention and adipose tissue, May exacerbate diabetes mellitus, Rare cases of adrenal insufficiency
Cannabinoids	Dorabinol	Improved appetite and weight gain in small studies	CNS effects (slurred speech, nausea, dizziness, sedation)
Cytokine Inhibitors	Pentoxifylline, Thalidomide, Suramin Monoclonal Antibodies to IL-1, IL-6, and TNF- α	Improved food intake and attenuation of protein loss in animal models	Clinical studies pending

CNS, central nervous system; GH, growth hormone; IGF, insulin-like growth factor; IL, interleukin; TNF, tumor necrosis factor.

Autonomy is the right of competent patients to make decisions over their care and implies that the physician must solicit these decisions. It was not until the mid-1960s, a time of vast societal changes and challenges to authority, that autonomy began to supersede the Hippocratic tradition with its emphasis on the authoritarian role of the physician. This principle is clearly outlined in a report from the President's Commission for the study of Ethical Problems in Medicine and Biomedical and Behavioral Research, which states: "The voluntary choice of a competent and informed patient should determine whether or not life sustaining therapy will be undertaken, while health care institutions and professionals should try to enhance patients' abilities to make decisions on their own and to promote understanding of the available options" (191). With regard to most treatments (operations, chemotherapy, radiation therapy), the patient's knowledge and experience may be very limited, and thus, the physician's recommendations may form as the sole basis for the patient's decisions. This is not the case with nutrition. People understand the role of nutrition in sustaining life, and it is often hard for a lay person to understand why parenteral nutrition may not be indicated or even harmful when the patient has no other source of nourishment. In such situations, it is the responsibility of the physician to thoroughly explain the reasons for withholding TPN.

The principle of medical futility often surfaces in discussion of nutritional support of the cancer patient, especially if the disease is advanced and unresponsive to therapy. There are four aspects to medical futility (192): (1) lack of physiologic rationale for the proposed therapy; (2) failure of the same therapy in a previous attempt; (3) all possible treatments for the underlying disease have failed; (4) the therapy will not improve quality of life or achieve a goal of care (such as living to see a particular life event). In the case of parenteral (and rarely enteral) nutritional support of the cancer patient, aspects 3 and 4 may be specifically applicable.

It should be noted that these principles, autonomy and medical futility, should govern decisions for both initiation and withdrawal of an ongoing therapy. As stated in the report from the President's Commission, "A justification that is adequate for not commencing a treatment is also sufficient for ceasing it. Moreover, establishing a higher requirement for cessation might

unjustifiably discourage vigorous initial attempts to treat seriously ill patients that sometimes succeed" (191).

Religious beliefs will often strongly influence decisions regarding nutritional support. Publicly stated opinions on the subject include: (1) a statement from the Archbishop of Canterbury that removal from life support was permitted if it was better to allow the patient to die (193). (2) a report from the National Conference of United States Catholic Bishops that stated that Catholics are not required to use extraordinary means when recovery is hopeless and only the burden of care remains, (194) and (3) a review of Orthodox Jewish rabbinical decisions that concluded "the imperative to preserve life, supersedes, with a few exceptions, quality of life considerations" (195).

For the gynecologic oncologist, management of the patient with an inoperable bowel obstruction due to peritoneal carcinomatosis is a difficult and recurrent problem. A recent review attempted to outline the role of parenteral nutrition in this population (139). TPN should be considered in only those patients with a good performance status, and careful attention must be paid to medical and symptomatic outcomes, as well as ethical considerations. It is interesting to note the views of patients on various life-sustaining treatments. In a study from the University of Michigan, 90% of women undergoing treatment for a gynecologic cancer could envision a time when they would refuse ventilatory support, but only 37% could foresee a time when they would refuse artificial nutrition (196). It is important for the physician and other members of the health care team to inform the patient and the family that in the terminally ill, provision of food and water by enteral or parenteral routes will not improve comfort (138,190) and, in fact, may add to discomfort (138,197–199). At Memorial Sloan-Kettering Cancer Center, TPN is used infrequently in patients with gynecologic cancer and bowel obstruction due to malignant carcinomatosis who do not receive any further anticancer therapy. TPN is used under these conditions only when it is judged that it will enhance the quality of life of a patient who is not at imminent risk of dying in spite of the widely metastatic disease. When considering the chance of improving the quality of life, the burden of TPN administration and monitoring and the risk of complications have to be considered.

Quality-of-Life Issues in Gynecologic Oncology

DANA CHASE ■ LARI WENZEL ■ RICHARD PENSON
JEANNE CARTER ■ DAVID CELLA

INTRODUCTION

Health-related quality of life (HRQoL) is an increasingly important endpoint in clinical trials and a fundamentally important issue for patients. Quality of life (QoL) is a multifaceted and complex paradigm that reflects patients' experiences with disease, treatment, and accompanying long-term sequelae (1,2). While a specific definition of QoL may require articulating the patient's status on physical, functional, emotional, and social well-being (3), it can also encompass the disparate aspects of patient demography (age, ethnicity, education, income), social circumstances (relationships and roles), and spiritual issues. It is no longer acceptable to pursue curative treatment with the hope of improving mortality without consideration of treatment morbidity and without including patient-centered decision-making and QoL implications. Therefore, this chapter provides an overview of state-of-the-science perspectives broadly incorporating medical interventions (e.g., recent clinical trials) that have influenced QoL and other patient-reported outcomes, and gynecologic cancer survivorship issues, including several challenging symptoms (e.g., fatigue, neurotoxicity, lymphedema) and long-term concerns (e.g., sexual dysfunction, reproductive concerns, emotional well-being).

QUALITY OF LIFE

QoL is an abstract, multidimensional construct that covers the subjective perceptions of the positive and negative aspects of patients' experiences. We all know good QoL, but it is rarely simple. It integrates symptoms, physical, emotional, social, and cognitive functions, and reflects the impact of cancer and the side effects of treatment (4,5). Figure 33.1 lists elements of QoL (6–8).

Considering well-being or QoL is as old as Aristotle's concept of eudaimonia, or "good." The first attempt to quantitatively measure the impact of cancer was described in 1949, when Karnofsky and Burchenal reported a simple 11 (0 to 10) point scale for the clinical evaluation of chemotherapy. This was simplified into the ECOG (Eastern Cooperative Oncology Group) Zubrod scale (0 = asymptomatic, 1 = symptomatic, 2 = functional for more than half the day, 3 = functional for less than half the day, 4 = moribund). Performance status probably remains the single most significant bias that contributes to the big differences between the results of phase 2 studies (9). Early QoL studies rapidly revealed considerable discrepancy between observers and between the doctor's and his or her patient's evaluation of the patient's QoL, and it became clear that any method for

FIGURE 33.1. Elements of quality of life. Note: ADL, activities of daily living. Source: Modified from Ferrell B, Smith SL, Cullinane CA, et al. Psychological well being and quality of life in ovarian cancer survivors. *Cancer* 2003;98:1061–1071; Gralla RJ. Quality of life of women with ovarian cancer. *Gynecol Oncol* 1995;59:231–242.

measuring QoL, quintessentially subjective, would have to rely on patients themselves and not caregivers (10). Patient-reported outcomes (PROs) are now widely considered an excellent methodology to evaluate the utility of treatment. A simple composite measure of clinical benefit (measurements of pain [analgesic consumption and pain intensity], Karnofsky performance status, and weight) was used as the primary efficacy measure in a small but randomized study that led to Food and Drug Administration (FDA) approval of gemcitabine in advanced pancreatic cancer (11). Quality-adjusted time without symptoms of disease or toxicity of treatment (Q-TWIST) was an important addition as duration of symptoms, where they occur in the trajectory of the disease, and their source (disease or treatment) all influence their perception and impact (12). Large randomized controlled trials incorporating QoL endpoints have reported that docetaxel is associated with less neurotoxicity than paclitaxel (13), and erythropoietin (rHuEpo) significantly impacts anemia and fatigue (14). As physical functioning deteriorates, relational, spiritual, and psychologic issues become relatively more important (15,16). QoL has been shown to predict survival in numerous disease settings (17,18). In the Heart and Soul Study, a study of outcomes in 1,024 patients with coronary artery disease,

depressive symptoms were more predictive of overall health than conventional measures of cardiac function such as ejection fraction and ischemia (19). Work conducted within the Gynecologic Oncology Group (GOG) has suggested that baseline QoL scores predict survival and may serve as an early barometer of patients who may or may not respond to aggressive treatment (20,21).

HRQoL is also recognized as a crucial component in medical decision-making research, for instance, if 2 treatments are shown to have equal efficacy, a HRQoL benefit could determine the preferable choice of therapy (22). Measurement and comparison of longitudinal changes in PROs are essential in evaluating clinical trials. Response-shift effects or the change in an individual's internal beliefs, values, and perception based on health changes is viewed as a recognized confounder. Therefore, response shift effects should be assessed and adjusted for in clinical trials, allowing for a cautious approach to ensure that detected changes in HRQoL are truly due to treatment, intervention, or disease rather than measurement error (22).

Quantitative measure of patient outcomes is dependent on the use of validated instruments of psychometric data. Such questionnaires, or scales, list items (questions about particular constructs) in related domains (dimension or focus of behavior or experience). Retesting between subjects and over time establishes reliability (test-retest, interobserver variation, and correlation with related instruments), responsiveness, and applicability (generalizability or external validity). Good scales have to be (a) internally consistent (similar domains report agreement—Cronbach's $\alpha \geq 0.7$), (b) stable (reliability coefficient), (c) equivalent or superior to other scales purporting to measure the same thing (kappa statistics), and (d) accepted by patients and experts. Approximately 500 instruments have been developed (23). Commonly used tools include the Functional Assessment of Cancer Therapy (FACT—with gynecologic and symptom subscales), the European Organization for the Research and Treatment of Cancer QLQ-C30 (EORTC QLQ-C30), Hospital and Anxiety Depression Scale (HADS), Profile of Mood States (POMS), Rotterdam Symptom Checklist (RSCL), MOS-Short Form 36 (SF-36), and Visual Analogue Scale (VAS).

The Functional Assessment of Cancer Therapy (FACT) instrument (scale) is a 27- (generic core) to 50-item compilation of specific subscales composed of physical, social/family, emotional, functional, and disease-specific well-being concerns (<http://www.facit.org/>) (24,25). The EORTC also developed a similar QoL instrument consisting of a core component applicable to all cancer patients and modules developed for specific cancer sites (26). EuroQol-5Dimension (EQ5D) utilizes a brief 5-item questionnaire covering mobility, self-care, usual activities, pain/discomfort, and anxiety/depression, and a thermometer VAS ranging from 0 (worst imaginable health state) to 100 (best imaginable health state) (26).

For much of the last decade, the research agenda has been dominated by the comparison of instruments that evaluate the harder to measure aspects of clinical care (Fig. 33.2) (27,28). These studies have helped develop tools that have allowed important randomized clinical trials to now report QoL data (13,29). Formalizing the evaluation of HRQoL is becoming established, with ongoing debate over methodology and the distillation of a minimum set of criteria for assessing outcomes in cancer clinical trials that inform decisions in clinical practice (30). New modeling approaches that account for nonrandom omission of data are beginning to be accepted (31). Evaluating QoL helps describe populations, predict outcomes, and guide decisions (trade-offs and gambles), and can screen for dysfunction, help allocate resources, and improve awareness as patients approach end-of-life issues (32,33).

A novel approach to PROs is now funded by the National Institutes of Health (NIH). The Patient-Reported Outcomes Measurement Information System (PROMIS) network, which

FIGURE 33.2. Health-related quality of life—measuring the grey outcomes. Black and white outcomes: PFS, progression-free survival; OS, overall survival.

is part of the NIH Roadmap Initiative, aims to improve how PROs are selected and assessed in clinical research. PROMIS is establishing a publicly available resource of self-reported health domain measures, including those specifically targeted to cancer. More information can be found at <http://www.nihpromis.org/> (24). Additional useful resources for QoL measurement include <http://www.facit.org/>, <http://www.isoqol.org/>, <http://www.euroqol.org/>, <http://www.cancer.gov/>, and <http://www.ql-recorder.com/>.

QOL OUTCOMES AND CLINICAL TRIAL UPDATES FOR ENDOMETRIAL, CERVICAL, OVARIAN, AND VULVAR CANCER

Integrated multidisciplinary care has appropriately become the necessary standard of the complex care of patients frequently in specialist centers, with goals of care changing over the course of the disease (Fig. 33.3).

Endometrial Cancer

Literature has identified quality-of-life data that may inform therapeutic choices for women with endometrial cancer. In an advanced endometrial cancer study, patients were randomized to whole-abdominal irradiation (WAI) versus doxorubicin-cisplatin (AP) chemotherapy. Although overall QoL did not differ between the 2 treatment groups, there were symptom-related

FIGURE 33.3. Holistic care.

differences (34). Specifically, WAI patients reported significantly higher fatigue than those who received AP chemotherapy for 7 cycles plus an additional cycle of cisplatin alone. Significant differences in functional alterations due to changes in bowel function were identified at the end of treatment ($p < 0.01$) and at 3 months ($p < 0.01$), with radiation associated with poorer scores. However, the AP group showed significantly higher peripheral neuropathy scores at the end of treatment and at 3 and 6 months posttreatment compared to the WAI group ($p < 0.01$). Therefore, although doxorubicin-cisplatin showed increased survival, the authors emphasized that the patients should be counseled regarding significant peripheral neuropathy that may have a significant impact on QoL.

Notably, QoL has also been evaluated in comparisons of laparoscopy versus laparotomy (35,36). In both studies, QoL was superior in the laparoscopy group. In the GOG LAP2 trial, which compared differences in QoL between those endometrial cancer patients who underwent comprehensive surgical staging via laparoscopic technique versus traditional laparotomy, patients treated by laparoscopy had a superior QoL through 6 weeks postsurgery compared to those treated by laparotomy, likely due to it being a less invasive procedure, resulting in less pain, faster recovery, and a small but significant reduced length of hospital stay. However, except for a significantly better body image in the laparoscopy than the laparotomy group, these differences were not sustained at 6 months.

Response patterns for the LAP2 QoL data were reexamined by conceptualizing patient reports by content domains and development of constructs (i.e., sexual function, quality of relationships, body image, and fear of sex). No differences were found between the surgical groups, but the quality of the relationship, younger age, and being married increased the likelihood of responding to the items and better sexual function. Factors such as age, relationship quality, body image, and pain may place women with endometrial cancer at risk for sexual difficulties.

Radiation therapy is recommended for patients with high-risk features or advanced disease and is commonly utilized to prevent recurrence (37). The Postoperative Radiation Therapy in Endometrial Carcinoma (PORTEC-2) study examined the effects of high-dose intravaginal radiation therapy (HDIVRT) versus external beam radiation therapy (EBRT) (38). In the PORTEC-1 trial, it was observed that those women receiving EBRT versus observation had increased bowel and bladder symptoms in addition to QoL changes even 15 years out from treatment (39). With this information, the authors became skeptical of the actual benefit of EBRT in low to intermediate risk women. Then in PORTEC-2, the patients who received HDIVRT were found to have better QoL (38). Subsequently, HDIVRT has been gaining favor as a treatment modality, with supporting research demonstrating less morbidity (37,40–42) and excellent recurrence-free and overall survival rates (43) in comparison to EBRT (38,44). However, vaginal toxicities were noted with HDIVRT (dyspareunia, vaginal dryness, tightness, and shortening of the vagina), but further research is warranted to understand how these vaginal issues translate directly to sexual function for these women.

Finally, in the realm of endometrial cancer, obesity and its potential effect on QoL cannot be ignored. In fact, Fader et al. examined the association of obesity (BMI) and various QoL subscales (45). These authors highlighted the significant association of obesity with poor QoL in an otherwise highly curative cancer. Future research examining the role of diet and physical activity interventions is encouraged.

Cervical Cancer

In treatment of advanced cervical cancer, QoL considerations are primary. Several studies have demonstrated important QoL

results that have influenced clinical trial paradigms. For example, a randomized phase 3 trial demonstrated that although there was greater toxicity in the cisplatin/paclitaxel (CP) regimen, there was no statistically significant difference in overall QoL scores between this treatment arm and the cisplatin (C) single-agent regimen. This finding, combined with the improved response rate and progression-free survival in the CP arm and a higher dropout rate in the C arm, suggests a worse outcome for the single-agent regimen. In this case, QoL measurement contributed to the conclusion that CP is superior to C alone with respect to response rate, progression-free interval, and sustained or improved QoL for patients treated with cisplatin versus cisplatin plus paclitaxel (20,46).

Several other trials have reported QoL as a secondary endpoint to use in addition to survival data when choosing chemotherapeutic regimens to treat advanced cervical cancer (47,48). These authors effectively argue that when determining if certain chemotherapy combinations may improve survival, it is critical to consider QoL, as toxicity may worsen. One such study prospectively assessed the impact of treatment with cisplatin alone (C), versus C in combination with topotecan (C+T) on QoL in patients with advanced or recurrent cervical cancer, and explored the prognostic value of baseline QoL scores. Results from this study, employing the FACT-Cx measure, indicated there were no statistically significant differences in QoL up to 9 months postrandomization, despite more hematologic toxicity in the C+T arm. The baseline FACT-Cx was also associated with predicting survival (48). This was the first advanced cervical cancer study to note that patient-reported QoL measures may be an important prognostic tool in advanced cervical cancer. Finally, in an analysis of 3 phase 3 trials, the physical well-being subscale proved to be independently prognostic of survival even when controlling for known contributing factors (49). These phase 3 trials have challenged a traditional study design for chemotherapeutic agents by incorporating PROs into the interpretations and implications of the relative value of these regimens. Clearly, QoL is a critical factor in palliative chemotherapy for recurrent and/or persistent advanced cervical cancer, where life expectancy is likely to be brief. Pelvic exenteration is one of the most radical, but potentially curative, treatment strategies for advanced or recurrent cervical cancer. The procedure is an *en bloc* resection of the pelvic organs (i.e., uterus, cervix, vagina, ovaries, lower urinary tract, and/or rectosigmoid colon). This procedure requires a motivated patient, with a good support network to assist in the recovery period (50). Provision of information and presurgical preparation for potential changes to a woman's body (i.e., sexual function and ostomy care) are crucial for postoperative adjustment (50,51). Technological improvements in imaging have allowed for better selection of patients (no distant metastases) most likely to benefit from this extensive surgical procedure (52). The best candidates are those who are younger and have recurrent cervical cancer and pathologically negative surgical margins (52). This being said, the adjustment to life postexenteration is particularly challenging and requires intensive preoperative counseling.

Ovarian Cancer

Several phase 3 clinical trials have included longitudinal assessment of QoL as a secondary study endpoint. This information continues to influence a comprehensive interpretation of results, clinical trial design, and clinical decision making. For example, in a study of suboptimally debulked advanced ovarian cancer, although the addition of interval secondary cytoreduction to postoperative chemotherapy resulted in no notable long-term difference, a clinically significant QoL improvement was seen in both arms at 6 and 12 months after starting therapy. Fewer

complaints of neurotoxicity at 6 months were reported among patients who did versus did not undergo interval secondary cytoreduction, likely due to the break in chemotherapy (53). In this study, it was also shown for the first time in ovarian cancer that baseline QoL scores could predict survival, attributed primarily to the lowest scoring quartile on the FACT-O. This has been demonstrated in other trials as well. Carey et al. described the Canadian experience of QoL and performance status as they relate to progression-free survival and overall survival in a frontline chemotherapy trial for ovarian cancer (54). Both global QoL and PS were associated with progression-free survival and overall survival, thereby confirming the findings of Wenzel et al. in the United States in 2005. QoL has also predicted survival for patients participating in a phase 3 trial comparing gemcitabine with pegylated liposomal doxorubicin (55).

A controversial randomized phase 3 trial in optimal stage III epithelial ovarian cancer showed that intravenous paclitaxel plus intraperitoneal cisplatin and paclitaxel significantly lengthened PFS and OS compared to intravenous paclitaxel and cisplatin (56). During active treatment, patients on the intraperitoneal arm experienced more HRQoL disruption, abdominal discomfort, and neurotoxicity than those receiving conventional intravenous therapy. However, only neurotoxicity remained significantly greater for intraperitoneal patients 12 months post-treatment, and generally for both groups QoL improved over time (57). Given the continued controversy regarding intraperitoneal therapy, QoL information will continue to provide clinically meaningful information from which to guide treatment decisions. Studies are currently being conducted to mitigate the added burden associated with intraperitoneal therapy while hopefully maintaining survival benefit.

Several additional recent phase 3 trials have incorporated QoL endpoints into advanced ovarian cancer clinical trials (58–63). For example, du Bois et al. compared paclitaxel plus cisplatin (PT) with paclitaxel plus carboplatin (TC) in patients with advanced ovarian cancer, evaluating QoL utilizing the EORTC QLQ-C30 questionnaire (59). There were significant QoL differences in favor of the TC arm, therefore leading to the conclusion that paclitaxel plus carboplatin is a more reasonable and better-tolerated treatment overall. In a subsequent study, Greimel et al. (62) examined hematologic and nonhematologic toxicity of the TC versus PT regimens and the effects of toxicity on QoL. Again, QoL was better in the TC regimen, resulting in confirmation that where 2 regimens have equal progression-free and overall survival, paclitaxel/carboplatin is preferable. A similar recommendation can be made from QoL data where it was demonstrated that gemcitabine plus carboplatin significantly improved PFS and response rate without worsening QoL (58). The relationship between cancer treatment efficacy, benefit, and QoL for elderly patients is also being studied. In one phase 3 trial comparing cisplatin and paclitaxel to carboplatin and paclitaxel, although QoL scores did not differ between elderly and younger patients, the elderly patients showed a higher rate of early treatment discontinuation. The authors speculated that this may be due to provider and/or patient unwillingness to continue treatment in the setting of toxicities, which might otherwise be managed differently in a younger population (64).

Finally, in 2010, Vergote et al. reported the results of a Gynecologic Cancer Intergroup Collaboration trial, which compared upfront debulking followed by chemotherapy to neoadjuvant chemotherapy (65). As the standard approach to treatment has historically been surgical cytoreduction followed by chemotherapy, this was the first randomized phase III trial of this alternative strategy. In this trial, patients completed QoL assessments using EORTC-validated instruments. The authors reported similar survival outcomes in the 2 groups, with both perioperative and postoperative morbidity being higher in the upfront surgery group. However, the QLQ-C30 global health scores were

not significantly different between the 2 groups. The HRQoL measurement in this study did not seem to correlate with the “toxicity” (morbidity/mortality) demonstrated with upfront as compared to interval surgery. Future publications will hopefully elaborate on the QoL data to help explain this finding.

In the approach to recurrent ovarian cancer, tumor control without compromising HRQoL should be the goal of therapy (62). There have not been any phase III trials reported by the GOG that involve QoL assessments for recurrent ovarian cancer. There are, however, multiple international trials. The Gynecologic Cancer Intergroup used HRQoL measurements in their large trial of carboplatin and paclitaxel versus carboplatin and pegylated liposomal doxorubicin for recurrent platinum-sensitive ovarian cancer (CALYPSO) (66). QoL was measured every 3 months for 1 year from the date of enrollment. The doxorubicin arm was significantly less toxic. Patients treated with carboplatin and paclitaxel on this trial had longer-lasting and significant peripheral neuropathy, chemotherapy side effects in general, and worse body image. In addition, there were worse physical functioning and global QoL scores in these women at 3 months, although these were modest and did not persist at 6 months (67). This trial demonstrated the importance and utility of QoL data to challenge standard of care in large randomized phase III trials. Furthermore, in a German trial of nonplatinum doublets with topotecan versus topotecan alone, QoL measurements were also used (55). In this study, the doublet therapy neither provided survival advantage nor demonstrated differences in QoL scores. Combined therapy was associated in general with higher incidence of hematologic toxicity, yet this did not seem to be reflected in the QoL data. However, a detailed description of the data is lacking. In general, it appears that HRQoL data in the recurrent setting is deficient in terms of detailed descriptions of QoL disruptions and numbers of studies including QoL measurements.

Some may argue that QoL measurement in the recurrent setting is of particular importance being that therapy will often fail. This argument relates well to another sentinel paper published by Rustin et al. in 2010 (68). This study examined the impact of early versus delayed treatment of recurrent ovarian cancer based on CA-125 measurements exceeding twice the upper limit of normal. In patients in whom the CA-125 result was masked, treatment was initiated at clinical or symptomatic recurrence. The findings suggested that early treatment did not improve survival and, unfortunately, time to deterioration in QoL scores was shorter by several months in the early treatment group. This was seen across almost all QoL subscales. The QoL data here are noteworthy.

Unfortunately, effective screening programs and/or individual tests have yet to be clearly defined for ovarian cancer. Although QoL measurement in clinical trials evaluating therapeutic options for ovarian cancer is common, its use in the screening literature is limited. More commonly discussed is the impact of false-positive screening on QoL in cervical or breast cancer. Most QoL data in ovarian cancer screening lie in populations at high risk, such as those with genetic mutations undergoing risk-reducing salpingo-oophorectomy (RRSO). And, in the RRSO population, screening is more a process of early detection or diagnosis rather than a true screening test.

In general, the data are mixed regarding the negative impact of these screening tests on QoL (69). The U.S. National Cancer Institute’s Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial was a large trial to determine whether annual screening tests could reduce disease-related mortality (69). For the ovarian cancer screening group, women underwent annual CA-125 blood tests and pelvic ultrasounds. QoL was also measured using the SF-12 Physical and Mental Component Scales at each assessment. A cancer-specific distress scale was also used to measure satisfaction with the decision to participate in the trial

as distress may indicate dissatisfaction and discomfort with the intervention of the trial. In this study, although not described as specific to ovarian cancer screening, participants with false-positive tests had higher levels of intrusive thoughts about cancer, yet this effect did not appear to be long-lasting. Women and participants with a first-degree relative with cancer were more likely to have these intrusive thoughts. The participants with false-negative tests were also less likely to comply with further testing. The authors concluded that in screening trials, it may be important to intervene on the part of the participants with false-negative results to decrease the potential stress involved in screening trials. Those assigned to the control group did not have statistically significant differences in HRQoL contrary to the belief that the mere ability to be involved in a cancer screening process alleviates stress associated with unknown risk for cancer.

There are several studies examining HRQoL in RRSO. In a cross-sectional study of 846 high-risk women, 44% had undergone RRSO instead of periodic gynecologic exams (70). Although “generic” QoL as measured by the SF-36 did not appear to differ between the groups, the RRSO group did report fewer concerns in general regarding their risk for cancer. Unfortunately, these women also had significantly more menopausal symptoms and worse sexual functioning relating to pleasure and discomfort than the women who underwent gynecologic exam alone. In 2009, Fang et al. described prospectively collected data on QoL, sexual functioning, body image, and depressive symptoms in 75 women undergoing either RRSO or serial screening (71). The women who underwent surgery reported poorer physical functioning, role limitations, pain, and social and sexual functioning at the 1-month assessment. Most deficits resolved by 6 months; however, the RRSO group had persistent menopausal complaints. Kahn et al. also published on the impact of ovarian cancer screening on QoL. In this study of 135 patients, abnormal ovarian cancer screening results was associated with a significant decrease in the Mental Component Summary form of the Short Form-36 (72). Finally, the GOG also published initial data regarding RRSO and CA-125 in women at risk for ovarian cancer (GOG 199) (73). The study included QoL measurement; however, the data have not been published. Future work should perhaps target the RRSO group in terms of pre-operative counseling, postoperative recovery, and treatment of menopausal symptoms.

Vulvar Cancer

Vulvar cancers are rarer than other gynecologic cancers and predominantly occur in older women (74). Radical vulvar excisions are associated with poorer QoL and lower sexual function (75). Surgical treatment of vulvar cancer requires inguinal lymph node dissection (unilateral or bilateral) to assess regional metastasis; and wound breakdown and other postoperative surgical complications can be high in these cases (76–78). The GOG conducted a small prospective trial to evaluate reduction of lymphedema with standard closure versus closure with a fibrin sealant (Tisseel®, Baxter Health Care, Deerfield, IL) sprayed into the inguinal lymphadenectomy wound during surgical treatment for vulvar cancer. In this study, 150 women newly diagnosed with vulvar cancer were enrolled and randomized to either the standard closure or the fibrin sealant closure arm of the study, with 137 evaluable cases. The incidence of lower extremity lymphedema (LLE) was not statistically significant between the 2 groups; however, LLE rates were found to be elevated (60%–67%) at 6 months’ postoperatively in both the intervention and control groups (79). This study challenged the validity of lymphedema rates cited in previous research using retrospective study designs (36%–51%

previously described in the literature) (80,81) and indicates that lymphedema rates may be greatly underestimated. Vulvar cancer set the groundwork for sentinel lymph node mapping, as lymphedema is a major issue among these patients. Nodal sampling seems to be a major contributory factor in lower extremity lymphedema (82).

CHALLENGES IN GYNECOLOGIC CANCER SURVIVORSHIP

Treatment side effects can influence short-term QoL for many women, and long-term QoL if sequelae persist or worsen over time. Recognition of and management for these issues can vary from simple strategies to improve QoL (i.e., managing nausea and vomiting) to complex psychosocial issues (e.g., reproductive concerns), for which clear guidelines may not exist. This section illustrates some of the current, potentially unique, and more complicated aspects of gynecologic cancer survivorship.

Pretreatment factors may influence a patient’s QoL both during and after treatment. Several authors have noted that QoL is affected by preoperative factors, such as education, lifestyle, general health, and obesity (83–85), all of which in turn may affect a patient’s ability to tolerate therapy. The interplay between cancer or cancer treatment symptoms and QoL is well documented in the gynecologic cancer literature (e.g., 86,87). Several prominent investigations deserve mention.

Cognitive issues—although there is a considerable and growing body of literature specific to cognitive impairment and fatigue during and after chemotherapy, only recently has this been considered within the gynecologic cancer cohort. For example, Hensley et al. were the first to study cognitive functioning prospectively in an ovarian cancer trial (88). Although they did not find significant decreases in cognitive functioning in women receiving paclitaxel, gemcitabine, and carboplatin in a phase II trial, they did note that highly educated women might suffer greater impairments, and thus, future trials should include cognitive functioning measures in their QoL assessments.

Fatigue—this occurs in 70% to 100% of patients with cancer, and is often underdiagnosed, inadequately treated, and hard to disentangle from other symptoms of physical compromise and psychological distress (89). Fatigue, during and subsequent to cancer treatment, is a related, prevalent, and understudied issue for gynecologic cancer patients. Treatable causes of fatigue include anemia, malnutrition, medications, infections, pain, depression, insomnia, muscle dysfunction, and anticancer therapy (90,91). In an important QoL investigation, in 2,370 anemic cancer patients undergoing chemotherapy, recombinant human erythropoietin significantly improved patient-reported functional capacity and QoL independent of tumor response (14). Many authorities also advocate either energy conservation or pushing apparent boundaries with graded exercise and cognitive-behavioral therapy (92). Psychostimulants, such as short- and long-acting methylphenidate, have been initially positive, but more rigorous studies have suggested that there is questionable benefit over placebo or daily telephone calls from a research nurse (93).

Neurotoxicity—an increasingly documented long-term problem that cause sensory loss, pain, loss of function, loss of mobility, and for some women, loss of professional and recreational activity. Platinum compounds, the mainstay of treatment for most gynecologic malignancies (94), are associated with cumulative myelosuppression (particularly thrombocytopenia), neurotoxicity, and nephrotoxicity, as well as severe nausea and vomiting (95,96). Neurotoxicity, anemia, and nausea/vomiting

all have well-known adverse effects on QoL. Paclitaxel in combination with a platinum compound is now considered the standard of care as first-line chemotherapy for advanced ovarian cancer (97,98). However, paclitaxel has a number of toxicities (e.g., granulocytopenia, neurotoxicity) that synergistically overlap those of the platins, and the coadministration of paclitaxel and a platinum compound can increase the frequency and/or severity of shared toxicities, especially neurotoxicity. Docetaxel is associated with significantly less neurotoxicity (99).

Administration of glutamine or the antidepressant venlafaxine may be helpful in cases of paclitaxel-induced neuropathy, and amifostine may provide protection from cisplatin-induced neuropathy (100,101). However, at present there appears to be no drug available to reliably prevent or treat chemotherapy-induced neuropathy (100,102). Therapeutic interventions for neurotoxicity remain controversial, with vitamins B₆ and E possibly reducing the efficacy of alkylator chemotherapy. Nonpharmacologic approaches to treatment of chemotherapy-induced neuropathy are based on patient education regarding potential neuropathic side effects, the impact of these side effects on performance of daily activities, and related safety issues (e.g., tripping in the dark, driving).

It is worth noting that a new, reliable, and valid patient-reported measure is now available to document symptoms of neurotoxicity. The FACT/GOG-NTX measure consists of 11 items assessing sensory, motor, and hearing symptoms as well as possible functional impact. It was administered to 263 advanced endometrial cancer patients prior to each of 7 cycles of chemotherapy. Results of this study indicated that the patient-reported sensory symptom scores (sum of 4 item scores) increased significantly over the treatment duration ($p < 0.001$) in the paclitaxel/doxorubicin/cisplatin (TAP) arm compared to the doxorubicin/cisplatin (AP) arm. It was also noted that as few as 4 sensory symptoms in the FACT/GOG-NTX subscale can be used to reliably and sensitively assess chemotherapy-induced neurologic symptoms in clinical oncology without compromising the psychometric properties of the overall scale (103).

Lymphedema—can be challenging for gynecologic cancer patients, with the highest rates occurring in women treated for vulvar cancer (104–106). It is a chronic, progressive condition (104). The specific incidence of lymphedema of the lower extremity (LLE) following treatment for gynecologic cancer, as well as risk factors for LLE development, are not well documented in the literature, in contrast to research on upper extremity lymphedema (105). Findings from a retrospective study demonstrated that women treated with radical hysterectomy for cervical cancer were at an eightfold increased risk of developing LLE (106). Lymphedema in patients undergoing lymphadenectomy for endometrial cancer has been reported in the 5% to 10% range (107,108), although prospective data are sparse. Nodal sampling has also been documented as a factor in the development of symptomatic lymphedema, with an increased risk after removal of 10 or more regional nodes during surgical staging (92).

The lack of incidence data, awareness of symptoms, and understanding of LLE has contributed to inadequate referrals and treatment delays (109). This can lead to women receiving treatment after lymphedema has progressed to a more chronic stage. Stages range from mild and reversible condition (stage 1) to chronic edema (stage 2), or a persistent condition with moderate to severe edema (stage 3) (104). A recent survey of lymphedema specialists found awareness of LLE and its symptoms among medical professionals and patients to be poor. LLE patients were less likely to be referred to or seen by a specialist within the first 3 months of experiencing symptoms in comparison to women with upper extremity lymphedema ($P < 0.01$) delays (109).

Studies examining the psychologic ramifications of lymphedema in other cohorts (i.e., breast cancer) note that signs and

symptoms may come as a shock if adequate information is not provided (110). Feelings of distress, anger, and helplessness emerge from limited and conflicting information (111,112). Many women are unaware of the risk factors, symptoms, and management of lymphedema (113). Furthermore, significant psychologic ramifications (i.e., anxiety, depression, and adjustment problems), as well as physical and sexual difficulties, have been described in the literature (114). Untreated cluster symptoms (i.e., heaviness, swelling, and numbness) of lymphedema may contribute to poorer QoL (115–117). Additional issues, including financial burdens (i.e., compression garments, medications, and bandages), limited clothing options, decreased activities due to restrictions from swollen legs, recurrent infection, and loss of work can also be problematic (118,119). Lymphedema can also be socially embarrassing or undermine confidence in appearance or body image (119). The chronicity of this condition also serves as a reminder of one's cancer history, possibly heightening fear of recurrence or advancing disease (120), and the required long-term management on a patient's QoL can be significant.

Mechanisms to identify these women (predictive risk factor model and symptom assessment) and educate the medical community (accurate incidence and risk factor data) are greatly needed to address this issue. A GOG trial will prospectively assess the prevalence of LLE following surgical staging and adjuvant therapy for gynecologic malignancy. This clinical trial will enhance our understanding not only of the risk factors for LLE, but also the implications of this chronic condition on the emotional well-being and overall QoL of cancer survivors, and will ultimately address this significant deficit in gynecologic oncology field.

Sexual dysfunction—various therapeutic procedures (i.e., surgery) for treatment of gynecologic malignancies can directly affect sexual functioning, depending on the anatomy involved (121), but treatment modalities have the potential to interfere with multiple aspects of sexuality, including body image, desire, frequency, satisfaction, vaginal dryness, dyspareunia, and a decrease in vaginal length. Dyspareunia, vaginal dryness, and loss of desire tend to be the most common sexual difficulties reported after cancer treatment (122–127).

For women surgically treated for gynecologic cancer, removal of the ovaries, uterus, cervix, vulva, and/or vagina may be necessary. These procedures can lead to damage to nerves and scarring or adhesions in the pelvic area as part of the healing process. When ovaries are removed, hormonal deprivation occurs, resulting in abrupt menopause and atrophy of the vagina for many women. Vaginal atrophy is associated with vaginal dryness, tightness, itching, burning, and pain during sexual activity or gynecologic examinations. Research on surgical treatment and sexual function demonstrates that hysterectomy for benign conditions does not appear to impair sexual function (128). Studies investigating sexual function after treatment for cervical cancer noted changes in lubrication, vaginal elasticity, pain, and arousal difficulties, much of which resolves by 1 year (129–131). However, vaginal dryness and decreased sexual satisfaction/interest have been shown to persist up to 2 years or more (130,131).

Many long-term survivors face the reality of surgical scarring and loss of body parts on a daily basis, resulting in abdominal and sexual sequelae (132–134). Individuals receiving treatment for advanced disease or bowel obstruction may require the placement of temporary or permanent ostomy(ies) for urine or stool. Management of these appliances requires practice and support from medical specialists and often other patients (135). Radiation therapy can also have long-term adverse effects on sexual functioning, including dyspareunia, vaginal stenosis, scarring, and fibrosis (136,137). These sexual consequences can have a negative impact on QoL and tend not to be uniformly discussed at follow-ups (138,139). This is particularly concerning since chronic fibrotic changes to the pelvis have been noted to worsen vaginal atrophy over time, in some cases up to 5 or more years post radiation therapy (140).

Sexual morbidity is associated with poor psychological adjustment and QoL in women treated for gynecologic cancer (141–143) both in the immediate post-treatment period (144–146) and in long-term survival (147,148). However, not all women are sexually active, with rates from 10%–50% in older ovarian cancer patients (116,138) compared to 77%–81% in younger patients (144–150). Many factors can influence sexuality, such as age, quality of relationship or health of partner (151,152). One study indicated that younger gynecologic cancer patients experienced greater difficulty with body image, resulting in impaired sexuality (153). Regardless of interest in future sexual activity, vaginal health concerns exist for all women and have the potential to interfere with comfort and compliance with gynecologic examinations if dryness is present. Research findings have noted that persistent, bothersome menopausal symptoms (i.e., vaginal dryness) place female cancer survivors at higher risk for distress and depression (125). Vasomotor symptoms can also be disruptive to QoL as well as sexuality by interfering with sleep and energy (154,155), and therefore require early assessment and management.

Simple strategies have been shown to be helpful in rehabilitating vaginal health and sexual function in cancer survivors by improving lubrication, moisture, and the pH of the vagina (156–158). Sexual/vaginal health promotion includes use of vaginal lubricants (usually water-based) and nonhormonal vaginal moisturizers. It is important to distinguish between vaginal moisturizers and vaginal lubricants, as patients and many health care providers are often confused about their respective uses and administration (124). Vaginal lubricants are used to aid in vaginal entry or penetration by decreasing dryness and friction, and thereby decreasing irritation and pain (124), whereas vaginal moisturizers (creams, gels, suppositories, or ovules) are not intended for sexual activity but to hydrate the vaginal tissues and improve pH (124,159). It is recommended that menopausal female cancer patients use a vaginal moisturizer at least 3 to 5 times per week to manage symptoms of vaginal atrophy, and to administer it prior to bedtime for optimal absorption. Lubricants should be used with all sexual activity (124).

For women with persistent vaginal dryness interfering with QoL, a low-dose vaginal estrogen may be considered, but many questions exist about hormone replacement in the setting of cancer. Low-dose vaginal estrogens may initially show a temporary increase in serum hormone levels, creating a complex and controversial issue for patients and medical professionals (160); however, these levels return to the normal postmenopausal range. This is not the case for systemic absorption of oral or transdermal administration of estrogen and testosterone (161,162). It is not unreasonable to discuss and consider hormonal supplemental options in select women within the gynecologic oncology setting that are suffering from unmanageable menopausal symptoms negatively impacting QoL (163,164). However, more safety data and long-term studies are greatly needed in cancer populations.

For treatment of dyspareunia, vaginal dilators can be beneficial in treating vaginal stenosis and adhesions (156,165). Dilator therapy has been recommended as the only modality meeting reasonable standards for evidence-based medicine in the treatment of pelvic radiation-induced sexual dysfunction (166). The theory behind vaginal dilator therapy is that it mechanically stretches the vaginal tissues, allowing for the secondary remodeling of fibrotic tissue, thus improving elasticity, but some have speculated that it may also cause improved blood flow through stimulation of the vaginal walls (158). The benefits of drawing blood flow to the pelvic floor were investigated in regards to the pelvic floor tone. Women with greater pelvic floor strength were found to have stronger arousal response (167). The belief is that the engorgement process needed for arousal is facilitated by increasing pelvic floor strength and drawing blood flow to the pelvic floor muscles (167,168). Pelvic floor exercises are also

recommended for awareness of how to maintain relaxation of these muscles during the dilator process or vaginal penetration, allowing for better control of these muscles, thereby decreasing pain associated with reflexively tightening (124). More research is warranted, but a combination of dilator therapy with pelvic floor exercises to get both potential benefits is a reasonable approach. One study evaluated the reliability of an instrument (the Vaginal Sound), which was designed to measure vaginal length. The Vaginal Sound is a simple, inexpensive, reproducible instrument that has demonstrated acceptable reliability and appears to be able to detect hypothesized changes in vaginal length (169). This instrument can be used to document the degree of vaginal stenosis associated with radical hysterectomy and radiation therapy plus or minus chemotherapy in women treated for cervical carcinoma. The ability to measure vaginal length and correlate vaginal stenosis with sexual function will provide a rationale for much needed interventional studies to maintain vaginal length and sexual function.

Embarrassment and fear have been shown to decrease compliance with dilator therapy, but in most cases, education and support can enhance compliance. Unfortunately, for many hospitals and office settings, it is not feasible or practical to have a sexual health program or professional on staff. Therefore, it is important to identify a referral network of local professionals with experience in treating sexual difficulties, which may include mental health professionals as well as gynecologists with expertise in treating patients with changes in sexual function (i.e., menopause) related to medical illness. Educational resources are also available to help patients achieve greater comfort with these issues.

It is important to note that limitations currently exist within the oncology field specific to accurate assessment and measurement of sexual/vaginal health issues in female cancer patients. Sexual dysfunction and symptoms in cancer survivors may differ from those experienced by women in the general population. Evidence-based research using validated empirical measures of sexual function is greatly needed in cancer populations. Many measures have been developed to measure sexual function (170), but the most frequently used measure in cancer cohorts has been the Female Sexual Function Index (FSFI). The Patient-Reported Outcomes Measurement Information System-Sexual Function (PROMIS-SF) has gained the attention of researchers. The FSFI has strong psychometric qualities but was only recently validated in a cancer cohort (171). However, scoring issues must be addressed to avoid reporting artificially low FSFI scores and estimates of female sexual dysfunction prevalence in those not sexually active (172). Short versions of the FSFI have also been developed in the general population (FSFI-6 SF) (173) and tested in the oncology setting (FSFI CA-6) (174) to facilitate screening for sexual dysfunction in busy clinical practices. The FSFI CA-6 results are very promising, with internal consistency reliability of 0.86 and Pearson correlation of 0.97 with the full FSFI (174).

The PROMIS-SF tool continues the work of the PROMIS network by providing a flexible and psychometrically robust measure of sexual function within oncology. Development procedures for the PROMIS-SF have included review of the sexual function measure literature, focus group methodology, and development of a conceptual model (175,176), with large-scale item testing, psychometric evaluation, validation, and translation underway (176). PROMIS-SF has been designed to be a brief assessment tool to reduce patient burden and allow for assessment of this important domain within future clinical trials.

Reproductive concerns—female cancer survivors coping with reproductive concerns have been shown to have poorer QoL (39). Gynecologic cancer can present before childbearing has been started or completed, during pregnancy, or can even arise out of pregnancy (gestational trophoblastic disease). Reproductive concerns can vary by site of disease, and some women

may have the option of conservative surgical management. For example, radical surgery was previously recommended for early-stage operable cervical cancer patients up to stage IIA. More recently, however, cone biopsy alone has become a therapeutic option for young patients with stage IA1 cervical cancer who wish to preserve fertility (177,178), and radical trachelectomy, initially received with skepticism because of the small but definite increase in risk of recurrence, is gradually gaining recognition and acceptance, performed both vaginally and abdominally (179,180). Some have also questioned whether the standard of care pelvic lymphadenectomy should be changed to sentinel lymph node biopsy (181).

However, many women will be medically unable to have fertility-preserving treatment, leaving the emotional ramifications of infertility to be dealt with as a cancer survivorship issue (182). Gynecologic cancer survivors have reported feelings of sadness and grief lasting more than 1 year posttreatment (125), with some feeling deprived of choices or misunderstood (183) in the setting of cancer-related infertility. Others have voiced feelings of stigma or being “less than a woman” due to loss of reproductive organs (184). A woman’s reaction will be contingent on her personal desire for a biologic child, the degree of fertility impairment, and the willingness to use reproductive assistance or family-building options. One study of women treated for malignant ovarian germ cell tumors found that reproductive and sexual functioning was encouraging, although emphasizing the importance of a stable relationship at the time of diagnosis (185).

One study investigating the emotional impact of fertility-preserving surgical treatment for early-stage cervical cancer (radical trachelectomy) found that reproductive concerns and anxiety persisted postoperatively over time for these women (144,186). Guidelines published by the American Society of Clinical Oncology highlighted the lack of research on the reproductive concerns of cancer survivors as well as the need for more information (187). In a cohort study of gynecologic cancer and BMT survivors, a large proportion (73%) indicated it would be helpful to speak with a reproductive specialist, but only one-third of the sample had done so (188). Gynecologic cancer survivors expressed a greater need for information about where to go or with whom to speak about these issues, which may have been connected with their perception of not having fertility options, despite the availability of reproductive alternatives (i.e., third-party reproductive options). Very little is known about whether patients are utilizing reproductive assistance or have knowledge about available resources or the emotional ramifications of seeking fertility/family building in cancer survivorship, but unmet informational needs about reproductive options have been associated with negative mood and increased distress (188).

Psychologic well-being—patients with gynecologic malignancies face an array of emotional challenges, many of which persist 5 to 10 years after diagnosis. Psychologic sequelae can include distress, depression, anxiety, fear, and social disruption. Distress extends along a continuum, ranging from common normal feelings of vulnerability, sadness, and fear to problems that can become disabling, such as depression, anxiety, panic, social isolation, and spiritual crisis. Recently the National Comprehensive Cancer Network (NCCN) advocated recording distress as the sixth vital sign using a simple thermometer (10 cm) VAS (189), given that 20% to 40% of patients have significant distress, and only 10% of them are identified and referred for psychosocial evaluation (190). Depression is the least recognized and least effectively treated psychologic problem in patients with cancer (191). In the context of life-threatening illness, diagnostic criteria for depression typically include a significant change in mood on most days for more than 2 weeks. Clinically significant levels of distress and depression, greater than what would be expected in the general population, have been documented in

gynecologic cancer patients. Specifically, higher levels of distress have been identified in the newly diagnosed, in those undergoing intracavitary brachytherapy (192), in patients with advanced or recurrent disease (6,193), and younger patients (193), perhaps due to the loss and adjustment many experience with sexuality, fertility, and premature menopause.

Psychologic shifts have also been observed in women following completion of cancer treatment. In a prospective study with ovarian cancer patients, depression levels were found to decrease 3 months after completion of chemotherapy; however, levels of anxiety were shown to increase (194), perhaps reflective of the uncertainty that many women face about possible recurrence and concerns of future prognosis. However, studies with long-term survivors (5 to 10 years) have shown that disease-free, early-stage survivors have resilience and adjustment over time, with an overall good QoL. Despite the identification of many psychologic difficulties within the gynecologic cancer experience, the literature reveals that many women are not using psychologic services (136), despite a need for cancer-specific support (195). It has been noted that patients may not be aware of or have access to supportive resources, but would utilize them if offered.

Psychologic care considerations—outcomes are improved by an integrative approach, only possible through a proactive collaboration with surgical, radiation, medical, and nurse oncologists working together with psychosocial support. Psychosocial support should include services such as emotional, spiritual, nutritional, genetic, and financial counseling, and general cancer information and support, as needed. At the core of a compassionate response there has to be both acknowledging and responding to physical, psychologic, and spiritual issues. An empathic response occurs when the clinician explicitly makes the connection between the clinical situation and how the patient is feeling. A compassionate response requires action, mobilizing the whole medical team to challenge fear and isolation (196). The medical interaction should be therapeutic on every level. Building a relationship takes more than asking questions. Courteous introductions and a genuine effort to establish rapport pay huge dividends. Consultations should have clear, explicit objectives. Avoid assumptions and be flexible, using focused but open-ended questions, frequently summarizing and screening for concerns. Find out how the illness affects the person. Information should be simple and clear and tailored to the patient’s understanding, with the goal of reinforcing realistic hopefulness and supporting shared decision making.

The very process of exploring a patient’s emotional symptoms can be therapeutic, but many patients may benefit from professional counseling, support groups, and/or medication. Meta-analyses indicate that preventive psychologic interventions in cancer patients may have a moderate clinical effect on anxiety but less on depression, and that group therapy is perhaps at least as effective as individual psychotherapy (197). Treatment of anxiety can include antidepressant and antianxiety medication (e.g., buspirone, clonazepam), counseling, and behavioral therapies (198). A wide variety of antidepressant medications with different mechanisms of action and adverse effects are available. Selective serotonin reuptake inhibitors (e.g., fluoxetine, paroxetine, sertraline, and citalopram) are usually well tolerated and can improve depression within 2 to 4 weeks in 60% of patients. The tricyclics (amitriptyline and nortriptyline) have a slightly longer onset of action but can be useful for patients with significant sleep disturbances. “Atypical antidepressants” (bupropion, venlafaxine, and mirtazapine) have a relatively rapid onset of action and paucity of adverse effects. Stimulants (methylphenidate and pemoline) provide the most rapid onset (hours to days). With respect to novel counseling methodologies, a recent psychosocial telephone counseling intervention was shown to improve QoL for cervical cancer survivors compared to controls (199). This type of intervention has promise for people unlikely

to access traditional services. However, counseling information and resources should be routinely provided to all patients.

CONCLUSION

QoL research activity in gynecologic cancer has increased substantially over the past decade. This has included key findings developed within and disseminated through national and international cooperative groups. These contributions have become more robust and influential as the study and science of QoL and other PROs have advanced. Consequently, future directions in gynecologic cancer QoL research are likely to include a continued focus on measurement science and trial interpretation to aid in treatment decision making, as well as provision of interventions to enhance QoL. For example, in endometrial cancer, we may see areas of active investigation that include the role of obesity as a comorbid factor in the development of this cancer, as well as the role of obesity on potential response

to treatment and survival. Cervical cancer investigations may emphasize identifying behavioral or social factors that influence uptake of the human papillomavirus (HPV) vaccine. With respect to this disease, additional QoL studies specific to outcomes and morbidity from multimodality therapy are anticipated. Areas of active investigation in ovarian cancer will continue to focus on evolving paradigms of care such as intraperitoneal therapy, treatment for an asymptomatic rising CA-125, and continual or intermittent therapy for recurrent disease versus therapy only for symptomatic progression. The QoL implications in each of these treatment considerations are paramount and should be systematically studied within well-designed trials. Further investigation is also needed in palliative care strategies for women with gynecologic cancer. This may include careful examination of the role of chemotherapy in the elderly, as well as interventions to reduce significant issues associated with advanced or advancing disease (e.g., bowel obstructions, neurotoxicities). In each case, evaluation of QoL and other PROs will serve a significant role in advancing gynecologic cancer care and survivorship.

End-of-Life Care

SUSAN ZWEIZIG ■ SARAH HUGHES ■ LYNETTE DENNY
■ JOANNA CAIN

The goal of end-of-life care is to provide maximal palliation of symptoms and maximal psychological support at the end of life, as part of the continuum of oncology care. Ensuring that our patients get the best care as the goal of medicine shifts from curing disease to relief of suffering is one of the obligations of health professionals. To do so effectively requires engaging not only the physicians and nurses who have been part of the oncology treatment, but also the skilled assistance of palliative care and hospice professionals with the patient and their caregiving network of family and friends. It is a particular challenge in low-resource settings, where many of the medications and support structures are limited or absent, making reliance on family and friends with guidance from mid-level or trained health assistants who may not have participated in whatever level of prior cancer care the woman received the best path to palliative care.

THE END-OF-LIFE TRANSITION

Discussions about the nature of disease, the status of treatment, and the expectation and side effects of treatment are an ongoing conversation in oncology care. With the lengthening of survival for even the most deadly gynecologic cancer, ovarian cancer, and the multiplicity of options for ongoing chemotherapy, the decision to limit chemotherapy or other interventions involves multiple conversations over time aimed at balancing the potential side effects of new chemotherapies or other treatments against the expected benefit and impact on quality of life for the patient. In the setting of continuing conversation between the health care team and the patient, with or without her significant support individuals, there is often a point at which the ongoing therapy aimed at disease control or cure has a harm to quality of life that is greater than any benefit—a point at which the transition to comfort-focused end-of-life care is more clear, although palliative care may well have been initiated for some symptoms prior to this point (Table 34.1).

The balance can be difficult, as Callahan points out: “The most fundamental problem with technological medicine is twofold: that it can give us a longer life and a slower dying and that it can keep us alive when we might be better off dead” (1). Patient perspectives on what constitutes high-quality end-of-life care reinforces the importance of interactions most physicians would identify, such as communication, accessibility, continuity, and emotional support, but surprisingly, oncology patients compared to terminal patients with other diagnoses more often hold on to a desire to maintain hope (2). As a health professional, keeping this door open while realistically portraying prognosis and options and pursuing palliative care can be the hardest balance of all.

The timing and expectation of death for cancer patients continues to change. Thirty years ago, survival from advanced stage ovarian cancer of more than 2 years was very unlikely, and now is routine. As a backdrop to this advance, the age of death in the developed world has steadily increased, as the major cause of death has changed over the past hundred years from sudden death from infection, trauma, and childbirth in the young to a slower decline from chronic illnesses, usually in advanced age. Cancers that previously caused a rapid death now follow a more chronic recurring course, which changes not only patient and family perceptions about the length of time until they need to deal with the issue of death, but offers a longer time to work through the phases of dying and the opportunity to bring to closure key goals for an individual. Even the gender and role of caregivers at the end of life are changing, and the role of men as caregivers for women with gynecologic cancers deserves special attention (3). The development of palliative care teams, usually in hospital settings, has added significant expertise to symptom management, discharge planning, and accomplishing improved end-of-life care (4). Engagement of gynecologic oncologists into these teams further improves the breadth of knowledge and team perspective as end-of-life plans are made. Given the prolonged course of many of these cancers, the advance planning for end-of-life care has both more time for consideration and can evolve as the patient’s prognosis changes. The frequency and timing of hospice referral has been studied in older women with ovarian cancer, and significant disparities in care have been identified. Although more older women received hospice care during the time period studied, the proportion of late referrals to hospice stayed the same. Similar to other studies, significant disparities in the use of hospice were seen depending on race and socioeconomic status. Timely hospice referral was identified as a significant area for improvement in the care of older women dying of ovarian cancer (5). A recent study showed that even in the absence of a prolonged course of illness, the treating health care team can significantly improve end-of-life care by informing the patient of imminent death, thereby increasing the likelihood of patients and families getting the resources needed at the time of death, with no increase in anxiety seen (6).

ADVANCE PLANNING FOR END-OF-LIFE CARE: REDUCING THE EMOTIONAL BURDEN ON SURROGATE DECISION MAKERS

Along with improved symptom management at end of life have come improved vehicles for ensuring that patients have their wishes represented in their care, in terms of legal documents, but

Table 34.1 Key Issues to Address When the Therapeutic Focus Shifts from Cure to Care

Issue	Examples
Communication about terminal nature of cancer should occur in the course of ONGOING communication	“We are not achieving the goals we set together with this chemotherapy” “The cancer is continuing to grow despite our efforts with this new agent”
Assess what the patient WANTS to know	“I would not continue any further chemotherapy at this point, but feel we should focus on relieving your symptoms. What do you think?” “Do you have questions about what we just discussed?”
Identify that, in fact, the patient’s condition is terminal, and particularly if asked directly	“Am I going to die of this?” “Yes, but our attention now needs to be focused on making whatever time you have as pain-free and active as it possibly can be”
Identify the goals that the patient wants to achieve	“Are there any special events or things that are on your agenda that we need to know about as we plan your treatment?”
Identify what resources the patient is planning to access (e.g., support systems as well as insurance coverage/hospice coverage)	“Have you talked to your spouse/partner/children/friends about your plans to be at home, and do they have ideas about how that will work?”
Make sure that the priority items for the patient are dealt with immediately	“What is the number one issue for you right now?”

also ensuring that surrogate decision makers adequately represent patient wishes.

Serving as a surrogate for a woman with advanced cancer who can no longer make her own treatment decisions places a profound burden on the surrogate. Advance planning can make the burden lighter. Both the public and health care professionals often underestimate the burden of serving as a decision maker. Formal measures of stress document that months after serving as a surrogate in a decision to withdraw life-sustaining treatment, the surrogate’s emotional stress levels remain remarkably high. One study found that the stress of serving as a health care decision maker was twice as high as the stress levels on households who had lost their homes to fire in the Berkeley-Oakland firestorm (7). Decision makers commonly report waking up at two in the morning and wondering if they made the right decision. They make statements such as, “It was the hardest thing I have ever done in my life.”

When patients have not previously documented their wishes about life-sustaining treatment, the stress levels of their surrogate decision makers tend to be even higher. When surrogates are guided by the patient’s written advance directive, their stress levels are about 30% lower when measured 2 months after a decision to stop life support (7). Surrogates who “stand by” and affirm the patient’s prior written instructions worry less about whether they made the right decision. Those who had never talked with the patient ahead of time felt the anguish of “deciding for” a woman they love. An important message to women with cancer who are reluctant to engage in advance care planning is that they are continuing to take care of the ones they love by completing an advance directive and lessening their burden.

THE ROLE OF TRADITIONAL ADVANCE DIRECTIVES

Advance directives provide a woman with a means to legally document her preferences about medical treatments in the event she is no longer able to make her own decisions. The legal details and breadth of clinical context vary substantially by state within the United States, and by country of the world, with some legal systems not supporting this type of advance direction for their health care (8). In many jurisdictions, these

documents allow the formal appointment of a surrogate who becomes the woman’s legally authorized medical decision maker in the event of future incapacity. Being asked to document one’s preferences for treatment in conditions like “imminent death regardless of treatment” and “persistent vegetative state” can be anxiety provoking for anyone. The context of a new diagnosis of cancer often makes completing an advance directive a statement of prognosis rather than planning for something that may or may not be needed, and perhaps overwhelming. It is difficult to combine conversations about advance care planning with initial discussions of curative treatment and creates a temptation to put off these discussions until they have no further treatment options to offer or the patient declines further curative treatment.

Waiting until the patient is gravely ill or near death to have these important conversations risks that the patient may become too ill to be able to make her wishes known. Without prior planning, the patient will not have appointed the surrogate of her choice. Without her guidance, family and friends may disagree on treatment decisions, which add further to family distress. In addition, patients and their loved ones often benefit from having advance planning be more of a process than an event. Having discussions with the patient about who should and should not be given medical information can naturally lead into who would be the most appropriate decision maker should the patient temporarily be unable to make decisions for herself. When the patient reveals strongly held value differences within her social network, or when she indicates that her most trusted surrogate is not her legal next of kin, the patient should be strongly encouraged to complete a written advance directive if that legal construct is available.

Advance directives are remarkably effective in allowing the patient to designate her choice of a surrogate decision maker. These legal instruments are also effective in silencing those whose wishes and values diverge from the patient’s. Advance directives are also helpful to focus end-of-life treatment decisions on what the patient would have wanted. Advance directives are effective in designating a surrogate, but are less effective in turning values into action, which require medical orders.

Advance directives alone may not be enough to ensure that patients’ wishes regarding life-sustaining treatment will be followed (9). In technologically developed countries, decisions about whether to use cardiopulmonary resuscitation, ventilators, antibiotics, and feeding tubes are an integral part of the care of

women with advanced gynecologic cancers. Most persons with advanced stages of cancer and other chronic diseases ultimately make a decision to forego some or all forms of life-sustaining treatment (10).

When a thoughtful decision has been made to forego attempts at resuscitation, it is most distressing to family members to have the patient receive unwanted cardiopulmonary resuscitation (CPR). Emergency medical personnel who might inadvertently be called need written medical orders indicating not to provide specific treatments like CPR. Without such medical orders, emergency medical services (EMS) in most circumstances must attempt all possible life-sustaining treatments. As patients move from one place to another, a uniform set of medical orders is needed to ensure the patient's wishes will be followed no matter what their setting of care.

One of the best-studied systems of medical orders to document advance care planning is the Physician Orders for Life-Sustaining Treatment (POLST) paradigm. The POLST document converts patient treatment preferences into written medical orders based on a conversation among health care professionals, the patient, and/or surrogates about treatment goals. The form transfers with the patient across care settings to ensure that her wishes are honored no matter whether she is cared for at home, in an ambulance, in a nursing home, or in an acute care hospital. A 1-year prospective study of nursing home residents with advanced chronic illness followed residents whose POLST forms included a Do Not Resuscitate (DNR) order and an order for comfort measures only. None of these patients received unwanted intensive care, ventilator support, or CPR (11). If such laws do not exist, health professionals taking care of women at the end of life should make sure that a patient's wishes, and the support needed through orders, are present to avoid the harm that unwanted resuscitation and increased pain can have not only for the woman but for her family. In some legal systems, assuring that a DNR order is in place is solely the responsibility of health care professionals (9).

In summary, women beginning cancer treatment often benefit from the first stage of advance care planning, which is formally appointing a surrogate decision maker who shares their wishes and values. Women with advanced cancer who wish to forego one or more forms of life-sustaining treatment need to have carefully constructed guidance to all other health care personnel who currently are, or in the future may, provide care in life's last chapter.

ROLE OF FAMILY IN DECISION MAKING

Given the sequential and repetitive conversations described above, the inclusion of family and other support persons is almost universal and clearly preferable. They are the ones with whom they have shared their lives and their dearest and deepest emotions. They are also the ones by whom the patient wants to be surrounded during the last phase of life. However, patients have the right to exclude or include whomever they wish in conversations. Also, medical events can be so acute that they trigger discussions with family members who struggle to consider what the patient might have wanted in that circumstance and are not clear about who should be the surrogate decision maker. Expert communication with the family then becomes the most critical means of ensuring that the patient's best interests are served and there is a broad understanding of issues. Unfortunately, research suggests that communication is not as effective as it needs to be in these circumstances. Fifty-four percent of families did not understand basic information (diagnosis, prognosis, treatments) after physician–family meetings in an intensive care setting (12). Well-structured discussions that focus

on the disease process, the goals of palliative therapy, and understanding the concerns of family members may help the family formulate decisions that support the dignity and choices that the patient herself would have chosen rather than create conflict that might impede an appropriate transition to a palliative care setting.

To prevent problems, it is wise to respect several rules:

- Always ask the patient if she has preferences in her contacts with friends and relatives. Often, she wants some to be more involved than others.
- Ask the patient for one or two contact persons to organize the communication with family and friends. Communicate essential information always in the presence of them or of other relatives or friends chosen by the patient. In this way, the family and friends are well informed and they share the same information with the patient. They can also help the patient with the evaluation of the information afterward.
- Never talk about the patient “behind her back.” If the physician does, and the patient finds out, the relationship of trust may be damaged. This also prevents the patient from thinking that the family knows more than she does, which can also strain family relationships.
- In countries where health care is a financial burden to the family, it is the responsibility of the physician to ensure that decision making concerning continuation of treatment or starting a treatment is based on the ethical principles of autonomy, beneficence, and nonmaleficence. This decision making cannot be driven by financial pressures alone.

At the end of life, we should expect emotional reactions by patients and their significant others, including family, to the inevitable lifestyle changes and impending death. It is the task of the physician to try to understand the thoughts and behavior of the patient regarding death and dying as well as her worries and unfinished emotional and personal business. Information on the patient's values and beliefs should be sought—even information about very personal matters like relationships and sexuality might be needed for a proper assessment of her situation. The patient has to know that she has the choice to what extent she wants to participate in this assessment and what information she is comfortable to share both with the physician or care team and with her family and friends. In normal life, family and friends often meet the spiritual and emotional needs of a patient, and the role of the health team is to support these relationships, not replace them.

UNIQUE CIRCUMSTANCES FOR DECISION MAKING: PREGNANT PATIENTS

A rare but particularly poignant context of end-of-life decision making is that of the pregnant woman with terminal, metastatic cancer in whom survival even to the end of a normal pregnancy is unlikely. The choices for palliative therapy (e.g., pelvic radiation for control of local bleeding and pressure) may directly impact the likelihood of fetal survival. The possibility of delivery of a newborn—particularly prematurely, with all the known consequences—without surviving to mother the child make the choices even more complex for the woman and for her family. The primary objective of care for the mother is alleviation of symptoms, and choices to decrease the level of palliative care in order to facilitate fetal development are considered only if strongly desired and pursued by the patient herself. Maternal autonomy in making such decisions has been supported by both ethical and legal reviews, and these confirm that the patient's wishes must guide decisions regarding fetal well-being, including accepting or not accepting caesarian section in the terminal phase

of disease (13). There is no role for withholding appropriate and maximal pain and symptom management simply because the woman has a concurrent pregnancy (14). The health care team carries a special burden in this circumstance to ensure that the patient has all relevant and unbiased information regarding harms and benefits of all potential options for her and for her pregnancy to maximize her ability to make choices.

In the absence of the ability of the patient to speak for herself, the surrogate decision makers must weigh not only her wishes regarding a premature timing of delivery of the child and invasion with a surgical procedure such as a caesarian section, but also the likelihood of viability of the fetus and the supporting family's ability and choices about caring for a significantly premature child. End-of-life directives for pregnant patients that specifically address these issues may be helpful in discussion and documentation of patient wishes (15). Some states and countries have special restrictions regarding decision making about limiting life-sustaining treatment in terminally ill pregnant women. In fact, 27 states have statutes that prohibit an out-of-hospital DNR order being written on a pregnant woman or otherwise have a "pregnancy limitation." The role of the woman in fixing the parameters for balancing fetal well-being against her own needs for alleviation of pain and suffering is central, both if she can speak for herself or in representing those wishes by surrogate decision makers, and it is her health care team's obligation to make sure that these are well defined and described, and that the patient's wishes about her health care (autonomy) are respected in the terminal phase of her disease.

MAXIMIZING PALLIATION: MANAGING SYMPTOMS AT THE END OF LIFE

Pain Control

The mainstay of pain management at any time, and even more critically at the end of life, is a careful assessment of the type of pain (nociceptive [somatic or visceral] or neuropathic), the level of pain, the location and referral of pain, and the actions that increase or decrease the pain. This assessment will need multiple repetitions, as the kind of pain and level are likely to shift with disease progression. The management strategy is to focus on not only the type and level of pain but also the level of consciousness and the level of activity that a woman would like to achieve, and to vary the strategies accordingly (16).

The World Health Organization's three-tier pain ladder starts with low to increasing levels of pain and increasing strategies from acetaminophen and nonsteroidal anti-inflammatory drugs to opioid analgesics for more severe pain. Usually using a 1 to 10 (10 being the worst) pain scale with patients fixes their position on the tier and suggests management strategy, although combinations from other levels or even within a level may be required for maximal comfort. Given that many gynecologic oncology patients are in the severe category (7 to 10) at the end of life, this might even include combining two opioids, particularly during pain syndrome escalation, to control the pain (17). In the course of adequate pain or symptom management, the anticipated side effects may shorten the time to death (principle of double effect), which is a well-recognized consequence of ensuring maximal palliative care. The ethical obligation is to alleviate the pain and suffering first and foremost, and the side effects that cannot be avoided (which rarely impact time to death simply because most patients already have substantial tolerance for narcotic pain medications) are accepted in this setting.

Pharmacologic measures to address severe nociceptive pain usually require narcotic medications. The options for administration are broad and can be tailored to the patient's circumstances.

As a principle that supports patient and family control, a means such as dermal, oral (pill, sublingual, and liquid), buccal, or rectal can make administration easier. With long-term sustained-release formulations, the goal is to establish adequate base pain coverage with every 8- to 12-hour dosing and adequate breakthrough pain coverage with an immediate-release form of the agents. Having the patient or caregiver track the amount and timing of breakthrough dosing can help adjust both the base and rescue dosing and timing. Sustained-release formulations are available for morphine, oxycodone, and hydromorphone (18). Drug dose escalation may be necessary to provide adequate pain relief. A modified release narcotic may take 2 to 3 days to reach a therapeutic level, whereas a transdermal patch may take 3 to 6 days, and a long acting medicine, like methadone, may take 5 to 6 days or longer (19). While titrating a long-acting narcotic, an intravenous (IV) formulation may be required to control pain. Once a patient's pain is more adequately controlled with a sustained-release formulation, the short-acting agent should account for only 5% to 15% of the total drug dose.

Methadone is another option that has been utilized and can be particularly helpful when morphine is not adequate or is problematic for individual patients. It has a variable conversion ratio and pharmacokinetics in individuals and is much more difficult to titrate and manage with other medications. Methadone may be particularly helpful in patients in whom neuropathic pain resistant to opioids is a significant part of the pain complex. The final option to avoid IV pain management is the transdermal fentanyl patch. This is particularly helpful, when stabilized dosing is reached, for individuals who require continuous baseline coverage, and it is useful in patients who are unable to tolerate oral medications. The downside is the long time to peak concentrations, which renders initial evaluation and titration of dosages difficult and requires significant use of short-term release opioids to cover (20).

The use of IV forms of opioids with patient-controlled analgesia pumps can be accomplished in the home setting if needed. The use of a basal IV infusion with patient-controlled boluses is the preferred method. Subcutaneous infusion of opioids can also be used, with near equivalent efficacy, and it can be more easily managed in some home settings (21). For all methods, titration to comfort is the goal, with management of secondary symptoms such as nausea or sleepiness as needed by the patient and within the context of her goals. The last few hours of life can be marked by both increased or decreased pain, and a strategy to address this needs to be in place as part of the pain control program.

The multiplicity of tumor-related and therapy-related pain syndromes that result in neuropathies from invasion, radiation, or other therapy often require additional therapies (21). Anticonvulsants are helpful adjuncts. The most commonly used would be gabapentin, which is routinely used for postherpetic, chemotherapy-related, and diabetic neuropathies. Clonazepam and lamotrigine also may be effective. Additionally, tricyclic antidepressants (e.g., amitriptyline, desipramine, nortriptyline) may be helpful for neuropathic pain as they also treat underlying depression, have their own direct analgesic effect, and potentiate opioid analgesia (23). α 2-Adrenergic agonists, usually clonidine, have also been effective adjuvant analgesics for neuropathic pain as they work through a different receptor from opioids and decrease sympathetic outflow related to neuropathic pain. Corticosteroids such as dexamethasone can provide additional relief, particularly for inflammation irritating nerve endings. For the extensive pelvic tumor invading the nerves in the pelvic floor, the use of sacral or regional nerve blocks, epidural pumps, or ablation of nerve roots may play an important role (24). Implanted programmable pumps for neuroaxial infusion have been shown to increase analgesia and decrease the side effects that systemic opioids cause (43, 44). Topical lidocaine patches may also provide local relief.

Mind-body and psychological approaches, such as guided imagery, have been explored for dealing with cancer pain. These have been shown to decrease pain and positively affect symptoms (25,26).

Pain control in some settings, usually low-resource settings, may be restricted because of laws that do not allow patients access to adequate narcotic pain medicine at home or lack of access throughout the country. For these settings, use of any available pain medications along with local therapy (heat, cold, massage) may help add comfort. The fact that many women globally still die in severe pain argues for significant advocacy by the gynecologic oncology community, both in the U.S. and globally, with ministries of health and other relevant settings to address end-of-life pain control.

Nausea, Vomiting, and Bowel Obstruction

The etiology of nausea and vomiting at the end of life can be related to medications, constipation, or brain metastases, but more often for gynecologic cancer patients, it is related to malignant bowel obstruction. Ovarian and endometrial cancers have a higher likelihood of developing obstruction with disease progression, and therefore for effective symptoms management, it is critical to distinguish the obstructed bowel from constipation/obstipation.

Since the majority of patients are already at risk for constipation from medications (opioids, serotonin antagonist antiemetics) as well as low motility of the bowel, initiation and continued reevaluation of a bowel regimen is an important part of effective palliation. If patients can achieve adequate oral intake, the addition of fiber in the diet and fluid intake can assist in management. Patients maintained on an opiate regimen should take a baseline bowel regimen including a stimulant, such as senna, with or without a stool softener (27,28). If constipation persists, rectal laxatives or osmotic agents such as the polyphenolic compounds can be added as needed, and higher doses of these may be required to resolve constipation (29). There is insufficient evidence to recommend one laxative over another, and therefore, choice of laxative must be based on interpretation of individual contributing factors and side effect profiles. Metoclopramide is FDA-approved for treatment of cancer-related and opioid-induced constipation and may be helpful as a prokinetic agent in patients with gastroparesis or carcinomatous ileus. Other strategies that have been investigated with varying success include opioid rotation and administration of naloxone (30,31).

If obstruction is diagnosed, the consideration for surgery should be limited to women in good overall condition with a single site of obstruction. Various studies have shown that advanced age, poor general health or nutritional status, diffuse peritoneal carcinomatosis, ascites, palpable masses, prior radiation, and multiple obstructed sites carry a higher mortality and morbidity (32,33). Careful selection of patients has been shown to not only achieve symptom relief but also extend survival. Preoperative evaluation to ascertain the likelihood of benefit for individual patients should include imaging procedures (Gastrografin enemas, carefully chosen use of computed tomograph, and limited upper gastrointestinal evaluations) that target the identification of multiple sites of obstruction. Failure to identify the presence of multiple sites of obstruction can lead to a failed procedure, with consequent increase in the pain and discomfort of the patient during the dying phase.

Symptom management is usually the path taken in the treatment of bowel obstruction at the end of life. Nasogastric tubes provide quick relief, but are uncomfortable, and some reports suggest that they are ineffective in longer-term management of symptoms. Gastrostomy tubes are generally more comfortable, but require surgical or radiology intervention that may not be desired by patients. For individuals with partial and complete bowel

obstruction and carcinomatous ileus, gastrostomy tubes can provide significant symptom management with just dependent drainage or suction (34). Left-sided omental caking may present an obstacle to successful percutaneous gastrostomy tube placement, and intraluminal stenting for relief of gastroduodenal obstruction can be useful in advanced ovarian cancer patients with significant upper abdominal disease (35). Distal rectal obstruction can sometimes be relieved through the use of stent placement (36,37), which is worth consideration. At the end of life, when the major objectives of treatment are quality of life and relief from the symptoms of obstruction, successful stent placement can avoid the need for laparotomy, with the associated significant morbidity and mortality that is seen in this group of patients. Stents are easiest to use in left-sided colon lesions and should be placed proximal to the dentate line for comfort (38). For many patients at the end of life, pharmacologic agents will be the mainstay of treatment for nausea and vomiting associated with bowel obstruction and carcinomatous ileus. Dopamine antagonists such as haloperidol are the drugs of choice for antiemetics in the setting of bowel obstruction (39). These agents can be associated with significant extrapyramidal side effects, which can be lessened or prevented with antihistamines, such as diphenhydramine, which also has antiemetic effects in patients with bowel obstruction. Additionally, hysocine hydrobromide and hysocine butyl bromide are helpful with patients experiencing colicky pain and nausea. Somatostatin analogues such as octreotide are well tolerated and can limit the secretions and motility and diminish the symptoms of bowel obstruction overall (40,41). Octreotide has the option of a long-acting formulation, which only requires monthly injections, and has been shown to assist in the setting of advanced ovarian cancer (42). Hospice Pharmacia formulates a suppository with Lorazepam, diphenhydramine, and Haloperidol that can be inserted rectally for easy drug delivery in outpatients with vomiting (43).

Finally, corticosteroids have been used to reduce inflammation, and potentially reduce the obstruction in some patients, and are worth a trial as part of conservative management. Dexamethasone in a dose of 4 to 8 mg per day for 3 to 5 days is generally used for this and additionally can potentiate the effect of pain medications and antiemetics (44). Improvement should be noted within 3 to 5 days if these agents are effective.

Several alternative treatments are worthy of mention, although not much data on their use exist in palliative care. Acupuncture, which has been found to be helpful in alleviating chemotherapy-related nausea, was associated only with transient improvement in symptoms of nausea in a small pilot of patients receiving palliative care for cancer (45). Medicinal cannabis has also been found to help with chemotherapy-related nausea. Dronabinol is a purified synthetic cannabinoid (delta 9 tetrahydrocannabinol) that is approved for use in the treatment of nausea and vomiting associated with chemotherapy; however, its side effect profile, including vertigo, xerostomia, dysphoria, and hypotension, is unacceptable to many patients (46).

Nutritional Management at End of Life

The value of end-of-life nutritional maintenance must be firmly set in the context of what the goal of the intervention is. Giving artificial nutrition in the dying phase of life has generally not been shown to prolong survival, adds risk, and may not enhance comfort (47). Families and patients can have cultural- and religious-based concerns about not providing “nutrition” in the dying phase, often framed as “starving” the patient, which need to be addressed. It is very important to explain to patients and families that hunger and thirst are symptoms that are experienced differently in healthy people from those who are seriously ill. Those who are near death are often comfortable even though they are no longer eating.

At times, earlier in the trajectory of the patient's illness, management of nutrition as a trial to achieve another palliative or quality of life goal, for example to maximize stamina for a special event with a limited time line for treatment, may be an appropriate strategy. In this context, nutritional support might be started as a trial to evaluate whether this can achieve greater palliation of symptoms or to reach a clearly defined goal of the patient, such as attending a specific event, and defined time lines need to be discussed with patients ahead of time to assess the efficacy of this strategy in meeting these goals. In a sense, it allows patients to try to meet the energy needs for the energy expenditure they have set as a goal that they are otherwise unable to accomplish.

The options for artificial nutrition are enteral if feasible and parenteral if not. Most patients at the end of life have tried increased oral feeding, but owing to low transit times with associated nausea and lack of appetite, have ceased trying to eat. If a time-limited option to increase appetite is desired, then corticosteroids such as dexamethasone can be considered, although their efficacy is limited. Additional appetite stimulants include progesterones such as Megace. Both can have a limited impact on oral intake. Diet supplements then form the basis for increasing nutritional input, including simple formulations such as instant breakfast or intact protein formulations with low lactose.

Other enteral feeding approaches generally focus on feeding tubes either placed under fluoroscopy via a nasogastric approach or surgically placed in the jejunum or the stomach. These use protein hydrolysates with timed feedings or continuous infusions (48,49). The discomfort of nasogastric feeding tubes sometimes prevents this means of enteral feeding from being effective, but does allow for easy removal. J tubes require surgical intervention in the abdomen, in which landmarks are possibly obscured by tumor, and placement must be evaluated in light of the potential issues with the type of tumor and the likelihood of surgical difficulty. In patients with low motility and partial obstruction, the use of enteral feeding formulations may allow the patient to meet her goals without requiring the cumbersome and more difficult to adjust total parenteral nutrition (TPN).

TPN remains the final option for attempting to improve nutritional status transiently in end-of-life care. TPN ties a patient to an intravenous line, costs more, and is associated with increased morbidity that can add to the burden of symptoms such as dyspnea at the end of life. It is often more than a support person can manage at home, and may obligate the individual to undesired nursing home or hospital care settings. Furthermore, IV access with ports in the face of terminal disease and often-compromised immune surveillance can result in infections that diminish access not only for TPN but also for needed pain control or other IV medications (50). This, therefore, must be understood in a framework that defines clear stopping parameters (failure to meet goals of symptom relief or improved stamina for an event) and a clear overall time line. In general, TPN is not of benefit in the end of life for patients with cachexia from metastatic cancer.

Ascites Management

For women with ovarian cancer, ascites (and associated pleural effusions) create continual pressure, pain, and diminished pulmonary capacity that significantly impact activities of daily life and quality of life in the dying process. Management relies on elements of constriction of influx and increasing efflux. The pathophysiology of malignant ascites is not only obstructed efflux through lymphatics in the diaphragm (51), but also increased production of fluid. The fact that the protein content of ascites fluid is high (85% of plasma levels versus 25% of plasma levels for transudates) suggests that the vessel walls are compromised. An emerging culprit is vascular endothelial growth factor (VEGF), which enhances vascular permeability (52). This

suggests that VEGF receptor inhibitors might have a role in the palliative management of this problem. VEGF inhibitors have been used intravenously and intraperitoneally to palliate symptomatic ascites in ovarian cancer, with some success (53,54).

The mainstay of ascites management, however, remains paracentesis, and its application has been improved through ultrasound guidance. The use of pleuracentesis kits and vacuum bottles allows this to be done in outpatient settings or even at the bedside at home with ease, and many patients are managed simply with once or twice weekly removal of 1 to 4 L in an office setting, often without fluid replacement (55). Use of the closed drainage system developed for pleural drainage (Pleur-X; Denver Biomedical, Golden, Colorado, USA) has been successful with malignant ascites as well and offers a method that can be managed by the patient and family (56). Large volumes of fluid (10 L) can be removed (57), but this must be balanced with colloid infusions and risks further diminishing of the intravascular albumin and protein concentrations (58), leading to worsening anasarca and associated symptoms.

Another common strategy in the management of ascites is the use of diuretics to diminish vascular volume and loss through the vascular tree. Spironolactone is the mainstay of managing ascites associated with cirrhosis and is worth considering for malignant ascites (59,60). Other diuretics can be considered as well, particularly furosemide, but their primary benefit may be the peripheral edema associated with hypoproteinemia. There have been no clear head-to-head studies of diuretics versus paracentesis and quality of life outcomes in these patients to guide therapy.

In the presence of a slow-growing refractory malignancy that requires frequent paracentesis for symptomatic relief, peritoneovenous shunts as well as the tunneled catheter described above can be considered. A retrospective study of Denver shunts in malignant ascites reported a complication rate of 38%, including occlusion and disseminated intravascular coagulation (61). More radical means, such as laparoscopically guided intraperitoneal hyperthermic chemotherapy, have a role in earlier palliative care but would rarely be applicable in the end-of-life setting (62).

Pulmonary Management

Among the most frightening symptoms for women and their families at the end of life are the symptoms of dyspnea and chest pain. Three etiologies stand out in metastatic gynecologic cancers: malignant pleural effusions, parenchymal metastases, and nodal/mediastinal metastases with airway compromise. Although quite different in etiology, some basic principles form the basis of symptom management. These include the use of oxygen, relief of bronchospasm, control of secretions, and measures to promote relaxation, which are helpful with all these etiologies.

Probably the most difficult issue to treat is pleural effusions, particularly as they compound the pulmonary constriction caused by ascites in ovarian cancer patients. Thoracentesis (with ultrasound guidance) gives immediate relief, but reaccumulations are common. Repeated thoracentesis may be a strategy appropriate to short-term management or if only needed every few weeks, with the 4% or greater risk of pneumothorax with each procedure as well as the concurrent discomfort (63). Alternatives are restricted to those who have recurrent symptomatic pleural fluid, in whom this is the primary source of symptomatology and survival is expected to be more than a few weeks. One option is a tunneled closed system pleural catheter, which can provide considerable relief without requiring more major surgery and is successful in greater than 80% of patients (64). Another option for these patients is chemical pleurodesis, now virtually always done with talc by direct application with video-assisted thoracoscopic surgery (VATS) or through a chest tube (65,66). Success is more limited in the setting of repeated prior thoracentesis,

with scarring that can make the procedure less effective. Any suggestion of a trapped lung or an endobronchial obstruction further diminishes success to the point that pleurodesis would not be a useful choice (67). Most individuals will have a fever and moderate to severe pain around the time of instillation, and complications include arrhythmias, pneumonitis, empyema, and respiratory failure. Such a procedure requires the patient to be in the hospital for several days with a chest tube and occasionally in the intensive care unit for observation overnight if a VATS plus talc procedure is done. This creates costs and side effects that must be weighed carefully against the benefits. Pleurodesis should be restricted to individuals in whom this intervention has a significant chance of alleviating the primary symptoms to avoid exposing women unnecessarily to pain and side effects that further burden their dying phase of life (68).

Management of pulmonary metastases in the end-of-life setting, even if solitary, is focused on symptom relief. Many parenchymal lesions are asymptomatic, but pleural irritation can be problematic with coughing as well as hypoxemia. Lymphangitic carcinomatosis is less common in gynecologic malignancies than in others, such as breast or lung cancer, but dyspnea and hypoxemia with the thickened septa and interstitial edema are the primary symptoms to be managed. The dyspnea associated with lymphangitic spread is often symptomatically greater than the actual pulmonary disease present (69). Strategies to treat these symptoms are attention to environment, and diminishing walking or activity requires doing simple activities of daily living by changing the environment. The use of a handheld fan for air circulation, nasal oxygen (with portable units), and trials of pursed lip breathing may all help. Certainly, consideration should be given to diuretic therapy if there is any component of fluid overload, and opiates, particularly morphine, are helpful (70).

Morphine, whether or not it is in use for pain control, has an important role in decreasing air hunger and dyspnea and has improved efficacy when combined with midazolam (71). Concerns regarding iatrogenic respiratory failure are common amongst caregivers when medicating patients for air hunger. Clemens et al evaluated respiratory parameters in palliative care patients with shortness of breath and found that titration of opioids alleviated symptoms and decreased respiratory rates without causing hypoxia (72).

Anxiolytics, although helpful for the anxiety component and commonly used as an adjuvant, can occasionally worsen symptoms by causing respiratory depression and a resultant increase in air hunger and should be used judiciously in addressing pulmonary symptoms. Acupuncture has been shown to improve symptoms of dyspnea in patients receiving palliative care for cancer when given for 4 weeks, with sustained benefit seen after treatment (45,70).

Airway obstruction and cough have similar symptoms, and some of the therapy is similar. Cough may be due to multiple issues, including conditions unrelated to malignancy such as asthma or sinusitis, and from gastroesophageal reflux, which is more common with ascites. Therapies tailored specifically to these issues, such as the use of inhaled or intranasal steroids, antihistamines, and proton pump inhibitors for reflux, are appropriate. Cough due to airway obstruction responds to narcotic suppression with morphine or codeine. Occasionally, steroid inhalers add additional relief from bronchial irritation induced by metastatic disease. Even humidifiers may be helpful for some patients, particularly for coughs from irritated mucosal linings from prior mediastinal chest radiation. Inhaled furosemide may be helpful in reducing dyspnea and inhibiting the cough reflex as well as preventing bronchoconstriction in asthma. In some cases, radiation therapy targeted to specific areas of obstructing disease in the mediastinum, with an obviously longer survival estimate, may be of value in managing symptoms. In summary, the therapies for pulmonary symptoms rely on supplemental oxygen, local suppression of inflammation, suppression of cough and air hunger through opiates, and removal of fluid compression as needed.

Central Nervous System Involvement: Management of Seizures, Brain Metastases, and Mental Status Changes

Mental status changes are usually present at the end of life, and management of these symptoms are often the key toward patients achieving their personal goals at the end of life, many of which center around being awake and conversant to bring closure with family and friends. Delirium is particularly distressing to family members who also are seeking closure with the dying patient. For both, the decline in function from a prior baseline heralds more losses to come and creates even greater anxiety. Etiologies can be metabolic abnormalities (sepsis, renal failure), innumerable drugs, and structural brain lesions, with obvious differences in approach to treatment. There are clear predisposing factors, including age, multisensory impairment, medical illness, depression, dehydration, and abnormal serum electrolyte levels, pertinent to the end stage of malignancies (73–75).

Understanding the nature of the delirium is important in addressing what may be more than one contributing factor. Assessing alertness, distractibility, the patient's ability to concentrate and talk easily, and simple cognitive disturbances of memory, reasoning, or perception all contribute to the delirium, along with specific neurologic deficits or neuromuscular activity that can point to central nervous system metastases. Laboratory and physical evaluation with infection, hypercalcemia, renal failure, hypoglycemia, hypomagnesemia, and hypoxemia being key conditions to look for (75–78). Tuma and DeAngelis (79) noted that with appropriate workup, a significant number of patients can improve their symptoms (68%), even when terminal.

Addressing electrolytic abnormalities and treating infection have value when the goal of a clearer sensorium at the end of life can be achieved. Drug-induced delirium may be caused by opioids, corticosteroids, benzodiazepines, or anticholinergic medicines. Opioid-induced neurotoxicity may present as sedation, hallucinations, cognitive impairment, delirium, or even as a seizure. If opioid-induced delirium is the diagnosis, then rotation of types of opioids used can be helpful in restoring function (80). If there are hallucinations and agitation, particularly in elderly dying patients, the use of antipsychotics may alleviate symptoms (81,82). Haloperidol, risperidone, and olanzapine were found to be equally effective in a Cochrane review. Typical doses include haloperidol 1.25 to 2.5 mg/day, risperidone 0.25 to 1 mg given twice a day, and olanzapine 4.5 to 8.2 mg a day (83). Given intravenously, haloperidol can be effective within 30 minutes and generally lasts for at least 4 hours. Given by mouth, the half-life of haloperidol is considerably longer and can be used in mild delirium states. The starting dose is 0.5 mg twice a day, which can be increased up to 3.5 mg a day and can be given as often as every 8 hours. It is important to remember that these drugs have the potential of lowering the seizure threshold, as the more common electrolytic abnormalities associated with prior chemotherapy such as magnesium deficiency also may be present and compound the risk. They can also prolong the QT interval and may lead to cardiac arrhythmia. Finally, some patients may benefit from combining drugs and including a benzodiazepine to decrease associated agitation. Some studies have noted that delirium in patients with advanced cancer more commonly requires more than one medication (84). The most commonly used are Lorazepam (up to 2 mg) or midazolam, which is preferred if a subcutaneous route is to be used (85).

Another source of delirium or abnormalities in central nervous system function is brain metastasis. Initial therapy after diagnosis is the immediate use of corticosteroids to decrease local edema and also headache associated with this. This may, in fact, be all that is needed if the patient has a very short time to live, as median survival with brain metastasis with steroids

alone is about 2 months. However, if a patient is otherwise functional and treatment could improve her overall quality of life, then targeted radiation therapy should be considered. For this use, generally 300 Gy total dose given in 30-Gy fractions is administered (86). For care at the end of life, more aggressive resection and radiation is generally not appropriate.

Control of seizures depends on the etiology of the seizures. The more common causes in gynecologic oncology patients are electrolyte induced, often hypomagnesemia or hyponatremia. Primary brain etiologies range from brain metastases to brain hemorrhage and stroke. Virtually all will be able to be controlled initially with Lorazepam, either intravenously or by mouth. Electrolyte repletion should be undertaken (87). Seizures associated with brain metastasis may be controlled with simply the decrease in inflammation with corticosteroids.

Local Comfort Measures

Many of the measures for comfort at the end of life are related to simple things that can escape notice but create comfort for the dying woman (88). The environment itself gives comfort if familiar things are around, including sounds, smells, and pictures that hold meaning for the woman. Smells themselves may provide comfort, such as aromasticks, which have been shown to have some benefit in a noncontrolled setting for nausea and sleep disturbance (89). Music has been found to strengthen the “living human document” that there is a musical memory and energy from hearing it and sharing it at the end of life that gives comfort (90). Assuring that the issues of access and fall prevention are addressed by a care team is important to the success of home care. Skin protection through rotation if the patient is bed bound and early identification and treatment of skin breakdown prevents unnecessary sources of pain and infection. Many patients derive great comfort from gentle massage, and virtually all benefit from human touch and presence. Developing a plan for passive (or active) movement during the day alleviates pain and discomfort from decreased mobility. Eye care with artificial tears or even hydrogel eye patches may be needed. Perineal care and the use of urinary catheters to eliminate skin breakdown in the perineum are commonly used when the patient is no longer mobile. Prevention of pressure ulcers prevents unneeded pain and suffering so an integrated skin protection plan is of value (91). Families and patients sometimes need “permission” from their health care team to make the environment home rather than a hospital at home. Yet it is the breeze from the window, the smells of home, the sights of loved ones rocking in a chair beside them that bring the most comfort—and the physician must actively support choices that make this possible at the end of life.

Management of Fistulas in the Terminal Care Setting

The fistulas encountered at the end of life from both the urinary system and the gastrointestinal system are often the most difficult for family and caregivers to deal with. The principles of management are simple but difficult to achieve. The options are diversion, containment, and closure, regardless of the site of the fistula.

Enterocutaneous fistulae can occur from every part of the bowel, but those from the small bowel have high output and are irritating to the skin. Diversion is rarely an option in the setting of terminal cancer, primarily because the intra-abdominal spread of disease is frequently the etiology of the fistula itself in association with prior therapies, such as radiation. Surgical diversion, if the patient is medically stable and surgery could be limited, has benefits solely to provide better control and better fit of pouches over the ostomy site than over a fistula site. As noted

by Marsden et al., this does not remove the problem, as there may still be a discharge from the site of tumor-related necrotic material that must be managed (92). If this is not possible, the only recourse—similar to bowel obstruction—is to attempt to diminish flow through the gastrointestinal tract with octreotide and then to minimize and manage skin irritation actively. Small bowel fistulae can be associated with significant skin irritation due to autolysis of the skin from digestive enzymes. If a post-operative fistula location is not amenable to coverage with a pouch, wound vacuum-assisted closure (VAC) devices may be of short-term benefit (93).

Large bowel fistulae, most commonly to the vagina, can be more easily diverted, and this is the first choice if the patient is medically stable. Even a simple loop colostomy can provide relief from the volume of vaginal discharge. However, some discharge usually remains. The use of metronidazole for tumor necrosis and discharge in the vaginal area relieves some of the anaerobic odors, and sitz baths and douches as needed to control odor are also helpful.

Vesicovaginal and ureterovaginal fistulae are primarily handled by diversion, if appropriate. The primary problem with diversion is the discomfort and management of new percutaneous nephrostomies, and for some patients there may be a component of renal failure that there is no desire to reverse. Additionally, nephrostomies alone may not be adequate for resolution, and the use of ureteral occlusion with coils and sponge pledgets may also be helpful (94). Local measures, including scrupulous management of pelvic and perineal hygiene, the use of adult diapers, and the use of creams such as 1% silver sulfasalazine or skin barriers, are primary measures. There are no effective vaginal means to control or contain the output. Various measures, such as the use of diaphragms glued to catheters or local tissue glues, have generally been ineffective in this setting.

Bleeding related to the pelvic/vaginal fistula or to vaginal recurrence can potentially be controlled by single fraction pelvic radiation (95), or if severe and causing significant distress with radiologic embolization. Local measures, such as Monsel's solution, have only limited efficacy and packing can add considerably to patient discomfort. So, try to pick an approach that fits both the overall status of the patient (if only a few days are likely, then the value of any intervention would be negligible) and the comfort and decrease in anxiety she might gain from addressing the bleeding.

Management of Bone Metastases

Bone metastases are rare in terminal gynecologic cancers, being primarily confined to unusually high-grade cell types, such as glassy cell malignancies, neuroendocrine tumors, melanomas, small cell malignancies, or clear cell malignancies. When they occur, however, the pain associated with bone metastases can be the most excruciating of all the symptoms to be managed at the end of life. Corticosteroids and nonsteroidal anti-inflammatory drugs may have a significant role in managing the inflammatory pain from bone metastases and should be considered as part of initial management. If the metastases are localized, radiation therapy on a palliative basis may supply additional pain relief, with a success rate of 24% to 50% total pain relief and 80% to 90% of patients noting relief of pain (96,97). Relief of pain may be immediate or it may require several months, which may make it less helpful at the extreme ends of life, and the use of anti-inflammatory pain medications during treatment may aid in symptom relief until the effects of radiation become evident.

Key aspects of treatment include ensuring that radiation fields encompass the entire area of bone involvement (98) and also the prevention of overlap with prior radiation fields. One of the key areas for treatment is the periosteum, in which the

pain fibers are particularly abundant. Multiple schemes have been used depending on the urgency, the general condition, and the overall expected survival time of the patient. There does not seem to be a difference between single-fraction versus multiple-fraction approaches, except for the need for retreatment with single fraction (99) if survival is prolonged. Also, if there is a longer life expectancy, consideration should be given to prophylactic surgical fixation of weight-bearing bones with greater than 50% cortical destruction or size greater than 2.5 cm prior to radiation therapy (100,101). Newer interventions, such as flexible nails and cement, may allow stabilization even in medically fragile patients (102). Another option for consideration is the use of osteoblast-affinic agents, such as strontium 89 or samarium 153, which deliver localized radiation to osteoblastic bony metastases. The primary problem in their use is bone marrow suppression, which often limits their use in patients with ongoing residual suppression from their prior therapies. These agents are not appropriate for use in hypercalcemic patients, and the pain relief is slower in onset, with duration of about 12 weeks. This option may require multiple doses to increase efficacy (103,104). Research with radiofrequency and combined techniques is rapidly accumulating, which may be of particular assistance with pelvic metastases and those for whom radiotherapy is not appropriate or has failed (104,105). New approaches with embolization and ultrasound strategies are also being researched, providing broader options for the future (106,107).

Psychologic Needs in Terminally Ill Cancer Patients

An important aspect of palliative care in terminally ill cancer patients is the recognition and treatment of psychologic symptoms to improve quality of life at the end of life. The understanding of suffering requires not just addressing physical needs, but also distress, existential concerns, and social relational worries, which contribute to overall suffering in terminal cancer patients (108). Health care professionals often ignore the role that religion and spirituality play in coping with terminal illness. Most patients consider religion or spiritual aspects to be at least some what important, and the majority report that their spiritual needs were supported minimally or not at all by the medical system (109). Referral to chaplaincy services or other integrative medicine services is deemed valuable by our patients, and assessing their desire for this should be part of psychologic assessment and treatment (110). This is an area in which little training and modeling exist, and the ability to address spirituality comfortably with patients is limited but it is important for health professionals to improve in discussing and addressing these issues (111,112).

Depression and anxiety occur in a high percentage of cancer patients, particularly as disease advances and curative cancer treatment fails (113). The prevalence of depression in cancer patients has been the subject of numerous studies, and the reported rates have ranged from as high as 58.0% to as low as 4.5%, with age, lower performance status, smaller social networks, and less participation in organized religious services all significant in predicting depression and anxiety (114).

Anxiety in terminally ill cancer patients has received less attention than depression. Anxiety commonly increases as patients become aware of both the relative ineffectiveness of medical treatments in halting the progress of their disease and, consequently, their limited life expectancy (115). The awareness of the inevitable death is likely to cause anxiety in terminally ill cancer patients. Breitbart et al. suggest that the incidence of both anxiety and depression in cancer patients increases with higher levels of disability, advanced illness, and pain (116). The closer the patient is to dying, the higher the score on depression and the lower the score on physical performance.

Although depression and anxiety are important to continually assess in terminally ill patients prior to death, data show that a relatively high percentage of terminally ill cancer patients suffer from psychologic distress a few weeks before death, which appears to be related to physical symptoms. Treating the physical symptoms maximally is the first task in addressing depression and anxiety. Standard treatment for depression and anxiety is effective in this population, and tricyclic antidepressants that additionally address neuropathic pain are reasonable choices. Lorazepam is often used for assisting in managing other symptoms but also provides relief for anxiety. Some integrative medicine solutions, such as aromatherapy massage, have been shown to assist in decreasing anxiety and depression (117). In summary, psychologic symptoms in terminally ill cancer patients need to be systematically assessed and considered by the care team in the overall decision making and treatment plan at the end of life. Treatment of anxiety and depression clearly also improves overall management of pain, as well as making the process of closure more possible for dying women. If patients can reconcile their concerns with psychologic and pharmacologic support, this will substantially remove the suffering from emotional distress for the patient and her family.

REQUESTS FOR HELP IN DYING

Sometimes patients ask to end their life because of fear of an inability to control suffering at the end of life or inadequately managed pain or suffering. In most countries in the world, the law forbids assisted suicide. In the Netherlands, Belgium, and the United States (State of Oregon), individuals have access to laws that make assisted suicide available for those experiencing unbearable suffering, and this access is highly regulated. Data from the Oregon experience (118) as well as the Netherlands (119) show that most patients do not follow through even with an expressed intent for assisted suicide.

Regardless of where health providers are in the world, this is a question that will come up directly or indirectly if actively caring for dying patients—and challenges our communication skills as few have been educated specifically for end-of-life discussions (120). Additionally, having such a discussion requires physicians to address for themselves their own understanding and barriers to discussing dying, futility, and assisted suicide (121,122). Dying patients expect and need at least a minimal level of emotional support, defined by them as compassion and treating the whole person and not just the disease (123). Set in this context, this conversation is an opportunity to embrace the compassion and acknowledgment of the whole person that is expected by the patient and to enhance understanding of the fears and the needs of the patient in the present. Patients who state that they would like “extra” prescriptions for pain medicine or anxiolytics, or who blatantly state that they are thinking of ending it all themselves or would like help in doing so, are usually asking for an exploratory conversation about how “unbearable” dying will be.

Even in the middle of a busy clinic, time has to be made for this discussion. Confirming that the patient’s request has been heard and confirming the patient’s importance to her health professionals is part of the therapeutic relationship. A consult room with the inclusion of whomever the patient wants to include (or not) is a better setting than an examination room, if available. Exploration with more open-ended questions, such as “Why do you feel you need this extra prescription right now?” “What do you think will happen that might make you think of (whatever phrasing the patient used)?” is a way to begin the dialog. Remembering that suffering is not only physical but also psychologic and spiritual is important to ensure that all dimensions of fear and questions are answered, or if unanswerable,

acknowledged as important. Follow-up questions that explore the patient's motivation are outlined in Bascom and Tolle's article (119). Exploring each fear and, more importantly, assuring that with maximal effort at palliative care this can be addressed (and how), and that the patient is not viewed as a burden and is valued, will open critical communication and provides an opportunity to address the underlying concern of the patient. In addition, this is an optimal time to introduce or reintroduce the importance of advance directives and to implement specific written orders regarding life-sustaining treatments if these are available to the patient (124). If this is an area of communication that is uncomfortable to the physician, then having another member of the team lead this discussion with the patient would be valuable, but with the specific assurance that respecting her wishes and continuing to care for the patient are still of importance to the physician who has been a critical member of that patient's care.

BEREAVED FAMILY AND FRIENDS

Medicine focuses on the individual care of patients, and the needs and issues of the social network that supports patients are often ignored. End-of-life care, however, engages that entire social network of family, friends, and often spiritual advisors and requires understanding their needs and roles as the patient nears the end of life. Families define high-quality end-of-life care as first achieving good control of symptoms for the patient, but they also weigh quality on how well the dying person was able to control decisions and whether the family members felt that they had to be constant advocates for the needs and wishes of the dying person. In addition, education and emotional support for the family and friends caring for the patient were seen as important (125). **Caregivers of cancer patients may neglect their own health and emotional well-being to care for their loved ones. This may manifest as greater levels of depression and anxiety.** All the members of this network of care for the patient experience high levels of stress, burden, and diminished quality of life, which can be helped with specific coping skills training (126). Caregivers who are able to accept and reframe the patient's illness feel less strain and feel more capable of solving illness-related problems, all of which will directly improve the care of the dying woman (127). **Since those caring for dying cancer patients may not make time to seek care for themselves, it has been suggested that oncology practices assess for caregiver distress. This can be done by any member of the care team, including a social worker, and referrals to caregiver resources may be beneficial (128).**

While the care and comfort of the families and friends of dying patients are not a direct responsibility of the oncologic physician, advocating for the development of support for this network for patients and providing access to such support are. In addition, regardless of whether the physician and primary oncology team are directly involved in the end-of-life care of the patient, acknowledging the patient's death and the team's concern for her family with a card or phone call to the family is important in closing the circle for the family as well as the primary oncology team.

CARE FOR THE CAREGIVERS

Within palliative care in general and end-of-life care in particular, there is a tendency for patients and relatives to demand and benefit from a more personal approach to their care. The model of complete cancer care in gynecologic oncology provides a great

deal of satisfaction and reward and naturally leads to satisfying and potentially longstanding doctor-patient relationships. The personal distress physicians and nurses may experience as patients die coupled with the intensity of contact in end-of-life care can lead to serious risk of depletion of the team's emotional resources and to resultant burnout. Physicians and nurses should be aware of the risk factors for burnout in order to prevent this serious threat to their health and to their work performance. In oncology, and especially in end-of-life care, the stressors appear to be strongly related to the social and interpersonal aspects of the job, including relationships with patients and coworkers on the team (129–130). Self-care and development of self-awareness have both been identified as vital tools for the oncology physician in the avoidance of burnout and should be considered a fundamental part of a physician's approach to the dying patient. Improvement in self-awareness facilitates self-care of the caregiver (131).

One of the best ways to understand and prevent emotional exhaustion and burnout is for physicians and nurses to be able to share their responses and feelings with others at work. This can be done by the organization of support groups at work where they can discuss what moved them and how they dealt with the situation (135–137). Improvement in physician communication skills regarding these stressful issues actually diminishes physician stress since the doctor-patient relationship plays an important role in this regard (138–139).

The participants get the opportunity to discuss the emotional aspects of the care of the terminal patient. This can include revisiting conversations that were held about death with patients and their families. The team listens and discusses how these emotional events affected the person involved. Especially for younger and inexperienced personnel, this type of guidance by "peers" is very important. For the more experienced members, the team meetings can establish a framework for junior members to learn from and emulate. Physician experience can result in diminished emotional involvement and appropriate distancing of relationships, thereby allowing the treating physician to appreciate the satisfaction associated with caring for patients at the end of life. Comments, advice, and help of colleagues are important factors in staying mentally fit—again, a message for all health professionals for all aspects of end-of-life care.

CONCLUSIONS

End-of-life care is a very important part of caring for women with cancer. It requires the total commitment of the entire health care team. It includes medical interventions to relieve suffering, but also psychosocial care. Communication skills are very important to ensure optimal end-of-life care, and also to relieve the stress on the caregivers (139). In this communication, the autonomy of the patient has to be respected. The caregivers must respect the delicate balance between professional and personal involvement. Communication not only involves the patient but also her relatives and friends. It is important that this communication take place in the presence of the patient as much as possible to avoid misunderstandings. Psychologic symptoms need to be routinely assessed and considered by physicians in the overall decision making concerning the end of life. Special attention must focus on anxiety and depression to ensure all domains of suffering are addressed.

End-of-life care in oncology does not mean that the physician has to postpone the inevitable as long as possible. The goal is quite simply to continue the expert and compassionate care the patient has received throughout her treatment into the maximal alleviation of symptoms and suffering at the end of life.
